Abstract. We present a survey of the recent research efforts in integrating model learning with model-based testing. We distinguished two strands of work in this domain, namely test-based learning (also called test-based modeling) and learning-based testing. We classify the results in terms of their underlying models, their test purpose and techniques, and their target domains.

1 Introduction

On one hand, learning (functional or behavioral) models of software and computer systems (e.g., hardware, communication protocols) has been studied extensively in the past two decades. Various machine learning techniques [Mit97, Alp14] have been adopted to this domain and new domain-specific techniques have been developed for model learning (cf. the chapters on (Extended) Finite Stat Machine learning in this volume).

On the other hand, testing has been the dominant verification and quality assurance technique in industrial practice. Traditionally, testing has been an unstructured and creative effort in which requirements and domain knowledge is turned into a set of test cases, also called a test suite, while trying to cover various artifacts (such as requirements, design, or implementation code). Model-based testing (MBT) [UPL12, UL07] is a structured approach to testing in which the testing process is driven by a model (e.g., defining the correct behavior of the system under test, or specifying the relevant interactions with the environment).

The focus of the present paper is precisely in the intersection of the above-mentioned two fields: learning (functional or behavioral) models and model-based testing. In this intersection fall two types of research:

1. *test-based learning*: various (active) learning techniques make queries to the to-be-learned system in order to verify a learning hypothesis. Such queries can be tests that are generated from a learned model. We refer to this strand of work as test-based learning or test-based modeling [MNRS04, Tre11].

https://doi.org/10.1007/978-3-319-96562-8_3

2. *learning-based testing*: models are cornerstones of model-based testing; however, complete and up-to-date models hardly ever exist. Learning can hence be used to create and complement models for model-based testing. We refer to this category of work as learning-based testing [MS11].

To structure our survey of the field we focus on the following classification criteria:

1. Types of models: different types of models have been learned and have been used for model-based testing. We distinguish the following categories of models: predicates and functions, and logical structures (such as Kripke structures, cf. the chapter on logic-based learning in this volume), finite state machines (including their variants and extensions, cf. the chapters on FSM and Extended FSM learning, as well as learning-based testing in this volume), and labeled transition systems. The distinction between variants of these models is not always well-defined and there are several property-preserving translations among them. However, this classification gives us a general overview and a measure of matching between different learning and testing techniques.
2. Types of testing: requirement-based and conformance testing are the most prominent uses of model-based testing. However, other types of model-based testing have also been considered in combination with learning; these include: integration testing, performance testing, and security testing.
3. Domain: test-based learning and model-based testing have been applied to various domains, such as embedded systems, network protocols, and web services. If a research result considers a particular application domain, we classify the result in terms of the domain, as well.

The rest of this paper is organized as follows. In Sect. 2, an overview of model-based testing is provided. In Sect. 3, the basic ideas behind model learning and their relation to testing are presented. In Sect. 4, we review the types of models that have been used in integrating learning and testing and survey the different pieces of research related to each type of model. In Sect. 5, we classify the test purposes and testing techniques that have been considered in combination with learning. In Sect. 6, we review the domains to which the combination of testing and learning has been applied. Finally, we conclude the survey in Sect. 7 by pointing out some of the open challenges in this domain.

2 Model-Based Testing

Model-based testing (MBT) is a structured testing technique in which models are used to guide the testing process. Specification test models can, for example, describe the input-output functionality of a unit (function, class, module, or component) [HRD07, MN10], specify the state-based behavior of a unit [UL07] or a system [VT14], or sequences of interactions with graphical user interface [YCM09]. Ideally such specification models have a mathematical underpinning, i.e., have a formal semantics; such formal models include algebraic properties,

finite state machines, and labeled transition systems. Once specification test models are in place, much of the testing process can be mechanized thanks to various MBT techniques and algorithms.

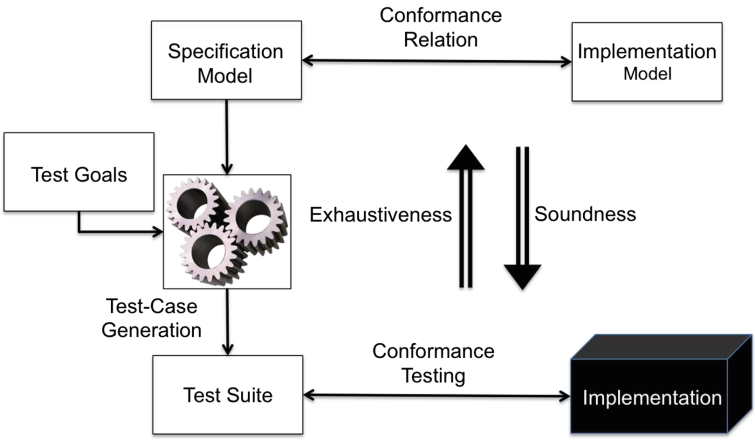

Fig. 1. An overview of model-based testing [ARM16, UPL12]

Figure 1 presents a general overview of MBT theory and practice. The underlying assumption of MBT is the existence of a formalization of the requirements in the form of a specification test model. This is a highly non-trivial assumption; models are often absent or incomplete in practice. Learning is a technique that can help reinstate the underlying assumption of MBT.

To put MBT on firm formal grounds, a common assumption is that the behavior of the implementation under test can be described by some (unknown) model with the same mathematical underpinning as the specification test model. This enables grounding the theory of MBT in a mathematical definition of a conformance relation between the specification model and the purported implementation model.

One of the most important ingredients of a practical MBT approach is a test-case generation algorithm that can automatically generate a test suite (a set of test cases) from the specification model (in an online or offline manner), taking into account the specified test goals. Then using a mechanized adapter the generated abstract test suite can be translated into concrete test cases that are executed on the system under test (which is traditionally considered to be a black box). The results of the test execution are then compared with the results prescribed by the specification test model.

The formal notion of conformance and the conformance testing algorithm are linked through soundness and completeness theorems. Soundness states that conformance testing never rejects a conforming implementation and exhaustiveness states that conformance testing is able to reject all non-conforming implementations. A sound and exhaustive conformance testing algorithm is called complete.

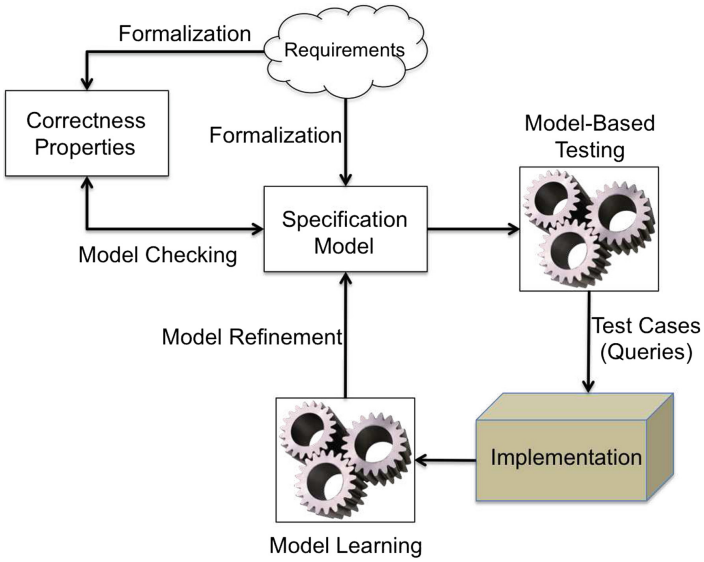

Fig. 2. Creating models for model-based testing

Specification test models can be learned from (reference) implementations and validated or verified by the domain experts, e.g., by manual inspection or model checking (as well as equivalence checking tools); Fig. 2 illustrates this process. Also incomplete or outdated models can be augmented or corrected (possibly with user feedback) using learning techniques.

Since the scope of this paper is the combination of model-based testing and learning, we only explore the part of the literature that serves at least one of the following two categories of purposes (cf. the chapter on testing stateless black-box programs in this volume for a complementary survey):

1. Model-based test-based learning, i.e., the use of model-based testing as a teaching mechanism in learning models, or
2. Learning-based model-based testing, i.e., the use of learning techniques to come up with models (of specification or implementation) in the model-based testing process.

3 Learning

In this section, we review the main ideas concerning model learning and their connections to (model-based) testing. We mainly consider active automata learning in the minimally adequate teacher (MAT) framework as introduced by Angluin [Ang87], since it shares clear common grounds with testing; for other machine learning techniques (some of which are also used in combination with model-based testing), we refer to [Mit97, Alp14].

Generally, this framework requires the existence of a teacher (called MAT) with which the *learner* interacts in order to learn (1) how accurate the currently learned model is and (2) how the system reacts to some new patterns that are of interest for improving the model. To this end, the MAT must be able to answer two respective types of queries: (1) equivalence queries, which check whether the currently learned model is an accurate model of the system under learning and (2) membership queries, which provide the system reaction to specified patterns of input. This setup is shown in Fig. 3. In fact, it illustrates an instantiation of this framework for black-box systems. Since ideal equivalence queries usually cannot be implemented, they have to approximated via model-based testing. Failing tests serve as counterexamples in such implementations, while the learned model and the system under learning are considered equivalent if they agree on all executed tests. The relationship between learning and testing is detailed further below.

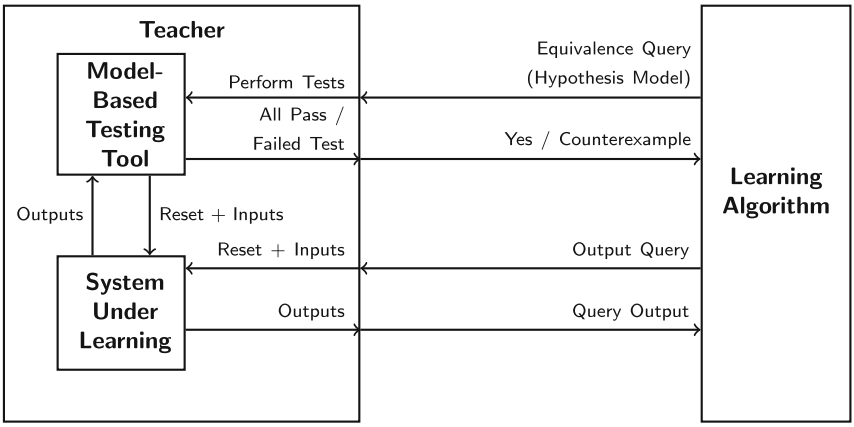

Fig. 3. Learning setup in the MAT framework. Figure adapted from a figure in [SMVJ15].

In the original L^* algorithm by Angluin, a deterministic finite automaton (DFA) representing an initially unknown regular language is learned. Membership queries correspond to the question whether some string is in the target language. In equivalence queries, the learner asks whether the language of a hypothesized DFA is equivalent to the target language.

These queries enable the learner to follow a two-step procedure in which it gains knowledge by posing membership queries. If there is sufficient information to create a hypothesis, an equivalence query is issued. The teacher either answers *yes*, signaling that learning is finished, or it responds with a counterexample to equivalence. Such a counterexample is then processed by the learner which eventually starts another round of learning.

Several variations of this general learning process have been proposed. All of them have in common that two types of queries are posed in an interleaved and iterative manner. As an example, consider learning of Mealy-machine models [Nie03, MNRS04, SG09]: instead of posing membership queries, the learner asks output queries [SG09], i.e., it asks for a sequence of outputs produced in response to a sequence of inputs. Analogously to L^*, equivalence queries are issued whereby a counterexample is a string of inputs for which the system under learning (SUL) and the current hypothesis produce different outputs.

3.1 Relation Between Learning and Testing

Early work relating testing and program inference predates Angluin's L^* algorithm. Weyuker [Wey83] proposed a program-inference-based test-adequacy criterion. She points out the importance of distinguishing between test-selection criteria and test-adequacy criteria. The latter should be used to assess if a passing test set contains sufficient data. For that she proposes to infer a program from a test set and deem it adequate if the inferred program is equivalent to both program and specification. Noting that checking equivalence is in general undecidable, she suggest that equivalence checks may be approximated by testing as is usually done for equivalence queries in active automata learning.

More recently, Berg et al. [BGJ+05] discussed the relationship between conformance testing and active automata learning, referred to as regular inference. Basically, both techniques try to gain information about a black-box system based on a limited number of observations, but with different goals. One technique solves a checking problem and the other a synthesis problem. They showed that a conformance test suite for a model m provides enough information to learn a model isomorphic to m. Conversely, observations made during learning a model m form a conformance test suite for m. This resembles the intuition behind Weyuker's work [Wey83]: a test set should contain information to infer a program equivalent to the original program.

Aside from the theoretical relationship, they referred to another connection between learning and testing. Since equivalence oracles do not exist in general, they can be approximated by conformance testing (as shown in Fig. 3). Hence, in practice a testing problem has to be solved each time an equivalence query is issued. Two examples of commonly used equivalence testing methods are the W-method [Vas73, Cho78] and partial W-method [FvBK+91], the latter aiming at improving efficiency. Both of these have for instance been implemented in the automata-learning library LearnLib [IHS15].

3.2 Test Case Selection vs. Query Minimization

Since exhaustive model-based testing is usually infeasible, it is necessary to select a subset of test cases based on some user-specified criterion [UPL12]. In other words, the number of tests has to be reduced. Because of the relationship described above, it can be concluded that a reduction of queries is required for learning as well. There are several possibilities for implementing

such measures. Most importantly, abstraction is essential for learning to be feasible. While abstraction is mostly done manually, techniques have been developed to derive abstraction automatically through counterexample-guided abstraction refinement [AHK+12, Aar14, HSM11]. In addition to that, we give three examples for ways to reduce the number of tests required for learning.

Algorithmic Adaptations. Following the work of Angluin [Ang87], shortcomings of the L^* algorithm have been identified and optimizations have been developed. A well-known example of such an optimization is the adapted counterexample processing proposed by Rivest and Schapire [RS93]. They extract a single suffix from a counterexample which distinguishes states in the current hypothesis. As a result, the observation table size and thereby the required membership queries are reduced.

Equivalence Testing Optimisations. Well-known methods for conformance testing are the W-method [Vas73, Cho78] and partial W-method [FvBK+91]. Thus, they may be used to check whether the current hypothesis is equivalent to the SUL. However, they suffer from two drawbacks. Firstly, they assume a known upper bound on the number of states of the SUL. Since we consider black-box systems, we cannot know such a bound. Furthermore, their complexity grows exponentially in the difference of the number of states of hypothesis and SUL. This makes the application in industrial scenarios impractical. Alternative ways of selecting tests should thus be considered. The ZULU challenge [CdlHJ09] called for solutions to this issue. Competing approaches were only allowed to pose a limited number of membership queries/tests. This resembles a setting in which the cost of test execution matters and equivalence has to be checked via testing.

Howar et al. [HSM10] describe that a different interpretation of equivalence queries is necessary in this case. Rather than testing for equivalence, it is necessary to find counterexamples fast. This is a reasonable approach, as learning is inherently incomplete anyway, because of its relation to black-box testing. Furthermore, they discuss their approaches to selecting test cases which are based on heuristics. They consider hypotheses to be evolving, i.e. testing is not started from scratch once a new hypothesis is constructed. Additionally, they base their test selection on the improved counterexample handling [RS93], combined with randomization.

Efficient equivalence testing has been addressed by Smeenk et al. [SMVJ15] as well. Since their SUL is too large for testing with the W-method, they developed a randomized conformance testing technique. It is based on a method for finding adaptive distinguishing sequences described by Lee and Yannakakis [LY94]. In addition to that, they selected a subset of the original alphabet which they tested more thoroughly. This is done to ensure that specific sequences relevant to the initialization of the considered application are covered although it would be unlikely to select them otherwise.

Another randomized conformance testing technique for automata learning has been presented in [AT17a]. It addresses coverage by mutation-based test-case selection whereby the applied mutations are tailored to the specifics of learning. Furthermore, stochastic equivalence checking has for instance been applied in learning-based testing to measure convergence [MN15].

Purely random testing, without taking heuristics into account, is a viable option as well. It has successively been used for experiments with the tool Tomte [AHK+12, AFBKV15]. However, Aarts et al. [AKT+14] also point out that while being effective in most cases, random testing may also fail if the probability of reaching some state is low. Still, quantitative analysis of learned models, e.g. giving some confidence for the correctness of the models, are mostly lacking. This is despite early work discussing such ideas [Ang87, RS93].

Domain-Specific Optimisations. Another important insight is that the inclusion of knowledge about the application domain can increase learning performance. This has for instance been shown by Hungar et al. [HNS03], who applied techniques such as partial-order reduction methods to reduce the number of queries. Another example of a domain-specific optimization is the modification of the W-method by de Ruiter and Poll [dRP15].

3.3 State Merging Techniques

A prominent alternative to learning in the MAT framework is learning via state merging. State merging techniques infer models from given samples, that is, sequences of symbols. This is usually done passively, i.e. without interaction with a teacher. Prominent examples are the RPNI algorithm [OG92] and ALERGIA [CO94]. In a first step, state merging techniques generally build a prefix tree acceptor (PTA) from the given samples. They then iteratively check nodes in the tree for compatibility and merge them if they are compatible. The tree is transformed into a finite automaton through this procedure. Depending on the actual algorithm, different techniques are used for the steps in this generic procedure and different types of models are created.

In the case of RPNI for instance, a deterministic finite automaton is inferred and samples are split into negative and positive samples. Furthermore, the PTA is built from positive samples while negative samples are used to check whether two nodes may be merged. ALERGIA requires only positive samples to learn a probabilistic finite automaton. Therefore, it augments the PTA with frequencies and bases its compatibility check on a statistical test.

The QSM algorithm is an interactive state-merging algorithm with membership queries [DLDvL08]. Hence, it is a query-driven State-Merging DFA induction technique. The induction process starts by constructing an initial DFA covering all positive scenarios only. The induced DFA is then successively generalized under the control of the available negative scenarios and newly generated scenarios classified by the end-user (membership queries). This generalization is carried out by successively merging well-selected state pairs of the initial automaton.

4 Models

In this section, we provide an overview of the kind of models that have been learned for testing. Most of the work concentrates on different types of finite state machines and labeled transition systems. Some researchers have considered other models, e.g. for stateless systems.

4.1 Finite State Machines

In [AKT+12,AKT+14], the authors use a combination of automata learning techniques to learn a model of the implementation, which is then compared to a reference specification model using equivalence checking techniques.

In [LGS06a], the authors use an approach based on L^* to learn Mealy machines, which is extended and more thoroughly described in [SG09]. Other work considers more expressive versions of Mealy machines [LGS06b,SLG07a], which include parameters for actions, predicates over input parameters and allow for observable non-determinism.

Margaria et al. [MNRS04] optimized the L* algorithm for generalized Mealy machines, i.e. Mealy machines that may produce a sequence of outputs rather than exactly one output in response to a single input. They report significant performance gains as compared to learning DFA models.

In [CHJS14,CHJS16], Cassel et al. consider generating models from test cases and present a framework for generating a class of EFSM models, called register automata, from black-box components using active automata learning. They introduce an extension to the L* algorithm called *SL** (for *Symbolic L**). However, they do not explicitly mention any particular testing technique. They only suggest using conformance testing in hypothesis validation (i.e., providing counterexamples). The SL* algorithm is available as an extension to LearnLib [IHS15], namely RaLib.

Ipate et al. [ISD15] propose an approach which, given a state-transition model of a system (EFSM), constructs an approximate automaton model and a test suite for the system. The approximate model construction relies on a variant of Angluin's automata learning algorithm, adapted to *finite cover automata* [CSY99]. In parallel with automata construction, they incrementally generate conformance test suites for the investigated models, using the W-method [Cho78] adapted to bounded sequences. These test suites are used to find counterexamples in the learning process. Their approach is presented and implemented in the context of the Event-B modeling language [DIMS12,DIS12].

Arts et al. [AT10] automatically extract finite state machines from sets of unit tests using an FSM inference technique, namely StateChum [WBHS07]. Then, the inferred FSMs are used to provide feedback on the adequacy of the set of tests and to develop properties for testing state-based systems. They use QuickCheck for testing and thus, consider generating QuickCheck properties. An FSM model is incrementally extracted from the test suite as it evolves.

In [RMSM09] a method for learning-based testing is presented, where the alphabet of the system under learning is progressively extended during the process based on previous interactions. This extension, and the knowledge gained about the system is used to further derive test cases. The method uses classic deterministic Mealy machines and the LearnLib for learning, and it is showcased with the Mantis Bug Tracker case study.

Relying on a heuristic approach to model inference, Schulze et al. [SLBW15] discussed an model-based testing supported by model generation. They propose to generate a model from manually created test cases in order to generate further tests from this model which possibly find undetected issues. In the case study, they report on manual effort for GUI testing a web-based system.

4.2 Labeled Transition Systems

Hagerer et al. [HHNS02] presented a technique called regular extrapolation for learning labeled transition systems (LTS) with inputs and outputs. For testing purposes, labels and states may have additional observations, i.e. parameters and attributes. Their technique starts with a set of abstract traces, either gathered passively via log-files or actively via testing. These traces are merged into a tree and then states with equivalent observations, i.e. equivalent attributes, are merged. Furthermore, a user may specify independence relations in order to simplify the model via partial order reduction. Model checking is used to verify if the learned model satisfies a set of Linear Temporal Logic (LTL) specifications.

Hungar et al. [HNS03] used the L* algorithm to learn LTS models with inputs and outputs that are input-enabled and input-deterministic. Several optimizations for reducing the number of membership queries are presented, most notably the application of partial-order reduction techniques that exploit domain-specific independence and symmetry properties.

Walkinshaw et al. [WDG09] introduce a reverse-engineering technique which infers state machines, in the form of LTS, from implementations. They use active state-merging techniques [DLDvL08] for learning a model based on program executions and model-based testing in refining the hypothesis model. The learning process starts with an initially small set of execution traces, based on which an initial hypothesis model is constructed. Then, iteratively, a given MBT framework automatically generates tests from the hypothesis model which are executed in the program. Any test conflicting the expected behavior by the model would restart the process to construct a refined hypothesis model. The process iterates until no more conflicts can be found by testing. For model inference, they use StateChum, developed by the authors [WBHS07], and use QuickCheck for MBT [AHJW06].

Walkinshaw et al. [WBDP10] use the technique introduced in [WDG09] and propose inductive testing to increase functional coverage in the absence of a complete specification.

Tretmans [Tre11] discusses both learning-based testing as well as testing-based learning. It is rightfully noted that intermixing the two directions is dangerous due to a risk of a circular dependency in the resulting testing process.

Most approaches by Tretmans, employ ioco-based conformance testing methods, and they treat both deterministic and non-deterministic models given as Mealy machines. The learning process is delegated to the LearnLib suite with custom extensions to facilitate better learning, Volpato and Tretmans [VT14] extend the Angluin's L* algorithm to work with non-determinism in input-output labeled transition systems. The ioco-based testing methodology is implemented in the TorXakis tool [TB03] and employs random model exploration to generate tests. The learning approach is further improved in subsequent work [VT15] which weakens assumptions related to the completeness of information obtained during learning. An important improvement is that the new approach does not require exhaustive equivalence checks.

Groz et al. [GLPS08] present inference of *k-quotients* of FSMs, but also of input output transition systems (IOTSs). They address the composition IOTSs and asynchronous communication between components. The latter is accounted for by introducing queues modeled by IOTSs.

4.3 Other Models

Meinke and Sindhu [MS11] apply the learning-based testing paradigm to reactive systems and present an incremental learning algorithm for Kripke structures.

For stateless behavior, predicates and functions provide a natural abstraction for the input-output functionality of programs. In [BG96], inductive program learning (and inductive logic programming) is used to learn the behavior of programs; the technique is used to generate adequate tests in order to distinguish the program under test from all other alternative programs that can be learned. In [HRD07], algebraic specifications of Java programs are learned. In [Mei04, MN10], functional models of numerical software are learned and the learned models are used for automatic generation of unit tests.

Walkinshaw and Fraser presented *Test by Committee*, test-case generation using *uncertainty sampling* [WF17]. The approach is independent of the type of model that is inferred and an adaption of *Query By Committee*, a technique commonly used in active learning. In their implementation, they infer several hypotheses at each stage via genetic programming, generate random tests and select those tests which lead to the most disagreement between the inferred hypotheses. In contrast to most other works considered, their implementation infers non-sequential programs. It infers functions mapping from numerical inputs to single outputs. Papadopoulos and Walkinshaw also considered similar types of programs, but in a more general learning-based testing setting [PW15]. Therefore, they presented the Model-Inference driven Testing (MINTEST) framework which they also instantiated and evaluated.

5 Test Purposes and Types of Testing

5.1 Behavioral Conformance Testing

Behavioral conformance testing is a common form of model-based testing, in which tests are generated in order to establish whether the behavior of the

implementation under test is "equivalent" to that of the specification model, according to a well-defined notion of equivalence. Typically behavioral conformance testing is integrated with model-learning in that the specification test models are learned and are subsequently used for generating a conformance test suite [VT15, ASV10]. However, in [AKT+14], an alternative integration is also explored. Namely, model learning is used to learn both a model of a reference implementation and the implementation under test and then equivalence checking tools are used to check the equivalence between the two learned model. This way conformance checking is performed in an intensional manner by comparing models rather than by generating test cases from the specification model and executing test cases on the implementation.

A case study following a similar approach is presented in [TAB17]. However, instead of comparing to the model of a reference implementation, learned models of implementations are compared among each other. Detected differences are considered to point to possible bugs which should be analyzed manually. Experiments involving five implementations of the MQTT protocol revealed 18 errors in all but one of the implementations. The system HVLearn described by Sivakorn et al. [SAP+17] follows a similar approach. It learns DFA-models of SSL/TLS hostname verification implementations via the KV algorithm [KV94]. Given learned models, HVLearn is able to list unique differences between pairs models and additionally provides analysis capabilities for single models. The authors reported that they found eight previously unknown unique RFC violations by comparing inferred models. Another example using a similar technique in the security domain is SFADiff [ASJ+16]. In contrast to the other approaches, it learns symbolic finite automata (SFA) and is able to find differences between pairs of sets of programs, e.g., for fingerprinting or creating evasion attacks against security measures. It has been evaluated in case studies considering TCP state machines, web application firewalls and parsers in web browsers.

These approaches to conformance testing between implementations can in general not guarantee exhaustiveness. In other words, if models are found to be equivalent this does neither imply that the implementations are equivalent nor that the implementations are free of errors. In testing of complex systems, however, the reverse will often hold, i.e. there will be differences. These may either help to extend the learned models in case learning introduced the differences, or may point to actual differences between systems. The discussed case studies showed that such differences can be exploited in practice, e.g., to find bugs.

5.2 Requirements-Based Testing

With the introduction of black box checking, Peled et al. [PVY99] pioneered a line of research combining learning, black-box testing and formal verification. In order to check whether a black-box system satisfies some formally-defined property, a model is learned with Angluin's L^*-algorithm and the property is checked on this model. If a counterexample is found, it either shows that the property is violated or it is spurious and can be used to extend the model.

To avoid false positives, conformance testing as described by Vasilevskii [Vas73] and Chow [Cho78] is also used to extend the model, i.e., to implement equivalence queries.

Following that, several optimisations and variations have been proposed. Adaptive model checking [GPY02a, GPY02b] optimizes black box checking by using a model of the system which is assumed to be inaccurate but relevant. Another early developed variation is grey-box checking [EGPQ06], which considers a setting in which a system is composed of some completely-specified components and some black-box systems. With regard to testing, the VC-method [Vas73, Cho78] and other conformance testing approaches, taking the grey-box setting into account, are used and compared.

Adaptive model-checking combined with assume-guarantee verification has also been considered for the verification of composed systems [HK08]. Furthermore, another variation of adaptive model-checking has been described by Lai et al. [LCJ06]. They use genetic algorithms instead of L^* in order to learn a system model. Their results show promising performance for prefix-closed languages.

Meinke and Sindhu [MS11] applied the learning-based testing paradigm to reactive systems and present an incremental learning algorithm for Kripke structures. Here, an intermediate learned model is model checked against a temporal specification in order to produce a counter-example input stimulus. The SUT is then tested with this input. If the resulting output satisfies the specification, then this new input-output pair is integrated into the model. Otherwise, a fault has been found and the algorithm terminates.

Following ideas of black box checking, a testing approach for stochastic systems is presented in [AT17b]. It focuses on reachability properties and basically infers testing strategies which optimize the probability of observing certain outputs. This is done via iterated model-inference, strategy generation via probabilistic model-checking, and property-directed sampling, i.e. testing, of the SUT.

5.3 Security Testing

Based on black box checking [PVY99], Shu and Lee had described an approach to learning-based security testing [SL07]. Instead of checking more general properties, they try to find violations of security properties in the composition of learned models of components. In following work, they presented a combination of learning and model-based fuzz testing and considered both active and passive model inference [SHL08]. This approach is more extensively described in [HSL08] with a focus on passive model inference. For this purpose they detail their state-merging-based inference approach, discuss the type of fuzz functions and the coverage criteria they used. Additionally, they provide a more exhaustive evaluation.

The compositional approach is also taken in [ORT+07], where several methods are used to study the security of cryptographic protocols, where learning by testing black-box implementations is one of the techniques employed. The

secrecy and authenticity properties are then checked on both the protocol specifications and the actual implementations through the learned model of the implementation.

Hossen et al. [HGOR14] presented an approach to model inference specifically tailored to security testing of web applications. The approach is based on the Z-quotient algorithm [PLG+14].

Cho et al. [CBP+11] developed a security testing tool called MACE. This tool combines the learning of a Mealy machine with concolic execution of the source code in order to explore the state space of protocol implementations more efficiently. Here, the learning algorithm guides the concolic execution in order to gain more control over the search process. When applied to four server applications, MACE could detect seven vulnerabilities.

5.4 Integration Testing

Tackling the issue that complex systems commonly integrate third-party components without specification, Li et al. [LGS06a] proposed a learning-based approach to integration testing. They follow an integrated approach in which they learn models of components from tests and based on the composition of these models, they generate integration tests. The execution of such tests may eventually lead to an update of the learned models if discrepancies are detected. Integration testing thus serves also as equivalence oracle. In following work, Li et al. [LGS06b, SLG07a, SLG07b] extended their learning-based integration testing approach to more expressive models. These models also account for data, through the introduction of parameters for actions and predicates over input parameters. Additionally, they also allow for observable non-determinism [SLG07a, SLG07b].

Groz et al. present an alternative approach to inference of component models [GLPS08]. Instead of learning each component model separately, they infer a *k-quotient* of the composed system and by projection they infer component models. With an initial model at hand, they perform a reachability analysis to detect compositional problems. If a detected problem can be confirmed, they warn that a problem exists, otherwise they refine the inferred models if the problem could not be confirmed. Testing is stopped when no potential compositional problem can be found.

In a similar setting as [LGS06a] and using the same algorithm, Shahbaz et al. [SPK07] described an approach to detect feature interaction in an integrated system. Basically, they infer models of components by testing, and execute the same tests of the composed system again. If the observations in the second phase do not conform to the inferred models, a feature interaction is detected.

Based on their previous works, Shahbaz and Groz [SG14] present an approach for analyzing and testing black-box components by combining model learning and MBT techniques. The procedure starts by learning each component's (partial) behavioral model and composing them as a product. The product is then fed to a model-based test case generator. The tests are then applied on the real system. Any discrepancies between the learned models and the system's real behavior counts as counterexample for the learned models, to be used to

refine the models. For a more extensive discussion of learning-based integration testing, see also the corresponding chapter in the volume.

In [KMMV16] a test-based learning approach is devised, where an *already specified system* under test is executed to find and record deviations from that specification. Based on the collection of these deviations, a fault-model is learned, which is then used to perform model-based testing with QuickCheck [AHJW06] for the discovery of similar faults in other implementations. Being a preliminary work, it uses classic deterministic Mealy machines in the learning process with the LearnLib implementation. The models utilized in this approach are rich state-based models with full support for predicates. It falls into the integration testing category in that overall goal of the work is to test implementations composed of different versions of components, some of which may exhibit deviations from the reference model.

5.5 Regression Testing

Hagerer et al. [HHNS02] and Hungar et al. [HNS03] consider regression testing as a particularly fruitful application scenario for model learning. With the possibility of automatically maintaining models during the evolution of a system regression testing could be largely improved.

Regression testing and learning is also related in [LS14], however, in a slightly different fashion and not directly connected to model learning. Namely, machine-learning techniques are used to identify, select, and prioritize tests for regression testing based on test results from previous iterations and test meta-data.

Selection and extension of test cases, consequently leading to the refinement of the software model used for MBT, is also considered in [GS16]. Additional tests are recorded from the Exploratory Testing process [MSB11] and checked to be covered in the existing MBT model. If they are not, the model undergoes a refinement procedure to include the new execution traces. This can be classified as expert supported continuous learning process to build an MBT model.

5.6 Performance Testing

Adamis et al. proposed an approach to passively learn FSM models from conformance test logs to aid performance testing [AKR15]. Since the learned models may be inaccurate, manual postprocessing is required.

5.7 GUI Testing

Choi et al. described *Swifthand* a passive-learning-based testing tool for user interfaces of Android apps [CNS13]. They interleave learning and testing: (1) they use the learned model to steer testing to previously unexplored states and (2) refine the model based on test observations. Their test selection strategy aims at minimizing the number of restarts, the most time-consuming action in the considered domain, while maximizing (code) coverage. The evaluation shows that *Swifthand* outperforms L^*-based and random testing.

6 Domain

Model learning and model-based testing has been applied to many different domains with different characteristics. In this section, we provide an overview of such application domains.

6.1 Embedded Systems

Embedded systems are a very suitable application domain for model learning and model-based testing; they often have a confined interaction with the environment through an interface. One of the earliest application of such techniques to the embedded system domain has been the application of model learning to telephone systems with large legacy subsystems [HHNS02,HNS03]. Meinke and Sindhu [MS11] applied their learning algorithm to a cruise control and an elevator controller.

Test-based learning (based on a variant of the well-known FSM-based testing, called the W-method) has been applied in [SMVJ15] to learn an industrial embedded control software.

The combination of learning and testing has also been applied in the automotive domain. In [KMMV16], the basic ideas about learning faulty behavior of AUTOSAR components is explored in order to predict possible failures in component integration. In [KMR] learning-based testing is applied to testing ECU applications.

6.2 Network and Security Protocols

Another application area often explored in the context of learning and testing is that of security protocols and protocol implementations. Using the abstraction technology described in [AHK+12] and Mealy machines learned through LearnLib, [FBJV16] reports on learning different TCP stack implementations. Instead of for testing, the learned models are used for model checking to verify properties of these implementations in an off-line fashion. A similar case study carried out in a security setting focused on SSH implementations [FBLP+17]. Model checking the learned models of different implementations revealed minor violations of the standard but no security-critical issues. In [MCWKK09], the learned protocols are used as an input for fuzzing tools in order to reveal security vulnerabilities. Learning-based fuzz testing has also been applied for the Microsoft MSN instant messaging protocol [SHL08,HSL08]. Furthermore, learning-based testing of security protocols is addressed in [SL07] as well.

The authors of [MCWKK09] learned a number of malware, text-based and binary protocols using some domain-specific and heuristic-based learning techniques. Aarts et al. [AKT+12,AKT+14] combined various learning techniques to learn and test the bounded re-transmission protocol and Fiterau-Brostean et al. [FBJV14] extended this work to fragments of TCP. Walkinshaw et al. [WBDP10] applied their inductive testing approach to explore the behavior of the Linux TCP stack.

Test-based learning has been extensively used to learn models of different sorts of smart-card based applications. Being black-box systems and typically specified using imprecise language, test-based learning helped to devise more precise models of such applications. In particular, the models of a biometric passport and a bank card have been produced this way, see [ASV10, AdRP13], respectively. In both works, a suitable data abstraction between the learning alphabet and the actual system inputs and output had to be developed to facilitate the learning process. This led to the development of Tomte, a framework for automated data abstraction for the purpose of real system learning [AHK+12, Aar14]. The learned model produced [ASV10] was also compared to the manually developed model for the conformance testing of the Dutch biometric passport [MPS+09].

6.3 Web Services

Raffelt et al. applied dynamic testing on web applications [RMSM08]. More concretely, they described a test environment *Webtest*, combining traditional testing methods, like record-and-replay, and dynamic testing. The latter provides benefits such as systematic exploration and model extrapolation, while the former eases dynamic testing by defining possible input actions.

Bertolino et al. [BIPT09] used test-based learning (based on finite state machines) to learn the behavioral interfaces for web services.

6.4 Biological Systems

Biological systems have been recently studied as instances of reactive systems [BFFK09]. This provides the prospect of using models of reactive and hybrid systems to replace in vivo and in vitro experiments on living organisms and cells with in silico experiments (e.g., replacing the experiments with model checking or model-based testing) [BFFH14, Col14]. In [AL13], test-based learning is used to learn hybrid automata models of biological systems (cell models). In [MHR+06], automata learning technique is integrated with requirement-driven engineering to create and improve models of biological systems.

7 Conclusions

Learning-based testing is an active research area that has produced impressive results despite being a relatively young discipline. Different systems in various critical domains have been tested successfully including controllers, communication protocols, web applications, mobile apps and smart cards. Every year new algorithms, techniques and tools are proposed in order to learn and test increasingly complex systems.

The prevailing concern in the domain of model-learning (in the context of testing) is the scalability and applicability to real systems. For such applications, abstraction techniques for input and output data are needed to support the learning process. The researchers are actively looking into automating this

process, which in many cases is still manual and requires either domain-specific knowledge, or apriori knowledge about the system under test. Several discussed papers either mention this as an issue, or provide some solution for it.

Another open issue surfacing in the described works is the treatment of richer models, both in the context of learning and testing. For example, stochastic models, or models that consider time or system dynamics. Such rich models bring new challenges in both research domains, moreover, they underline the scalability issues mentioned above.

Completeness (or a quantified approximation thereof) is another major concern in this domain. A property of algorithms in the MAT framework is "that a learned model is either complete and correct, or not correct at all" [VT15]. Note that in this context, correctness expresses that the learned model and the system under learning agree on all possible inputs. In [VT15], this property has been dropped by learning an over- and an underapproximation and preserving ioco-conformance during learning. In other words, there are two learned models which may not agree with the system under learning on all inputs but which are in a conformance relation with the system. However, such an adaptation may not be possible for all types of models. Steffen et al. [SHM11] also mention this property, stating that it must be accepted and that incompletely learned models may still provide benefits in certain scenarios, e.g., for test-case generation [HHNS02].

Scenarios like black-box checking [PVY99] on the other hand suffer from incompleteness[1]. They can guarantee that a verified property either holds or the number of states of the system is larger than an assumed upper bound. More quantitative measures of correctness would be useful for this type of verification such that, e.g., statistical guarantees could be given with a certain confidence. Although already early work discussed such matters, there has not been much research in this direction. In fact, Angluin considered learning without equivalence queries in a stochastic setting in her seminal paper [Ang87]. Furthermore, Rivest and Schapire also gave probabilities for learning the correct model [RS93]. Despite its practical usefulness, recent work usually does not assign probabilities or confidence levels to the learning result, also in case stochastic (testing) strategies are applied.

Testing has always been a challenge due to (1) its incompleteness by nature, (2) the lack of good specifications and (3) by its high demand for resources. With the growing complexity of the systems-under-tests this process is not going to be easier. Learning-based testing offers an opportunity to master this complexity with modern learning-based techniques. It represents a natural evolution of testing: with the trend of our environment becoming "smarter", e.g. smart homes, smart cars, smart production, smart energy, our testing process needs to be smart as well. We are seeing the advent of smart testing.

Acknowledgments. The insightful comments of Karl Meinke and Neil Walkinshaw on an earlier draft led to improvements and are gratefully acknowledged.

[1] The authors also briefly discuss stochastic properties of Mealy machines, though.

The work of B. K. Aichernig and M. Tappler was supported by the TU Graz LEAD project "Dependable Internet of Things in Adverse Environments". The work of M. R. Mousavi and M. Taromirad has been partially supported by the Swedish Research Council (Vetenskapsradet) award number: 621-2014-5057 (Effective Model-Based Testing of Concurrent Systems) and the Strategic Research Environment ELLIIT. The work of M. R. Mousavi has also been partially supported by the Swedish Knowledge Foundation (Stiftelsen for Kunskaps- och Kompetensutveckling) in the context of the AUTO-CAAS HöG project (number: 20140312).
