

Disclaimer : A beautiful and much simpler proof from Wojciech Czerwiński and Łukasz Orlikowski will soon be available on arXiv.

The Reachability Problem for Petri Nets is Not Primitive Recursive*

Jérôme Leroux

jerome.leroux@labri.fr

Abstract

We present a way to lift up the tower lowerbound of the reachability problem for Petri nets to match the Ackermannian upperbound closing a long standing open problem. We also prove that the reachability problem in fix dimension is not elementary.

1 Introduction

Vector addition systems with states [5], or equivalently vector addition systems [6], or Petri nets are one of the most popular formal methods for the representation and the analysis of parallel processes [3]. The central algorithmic problem is reachability: whether from a given initial configuration there exists a sequence of valid execution steps that reaches a given final configuration. Many computational problems reduce to this reachability problem in logic, complexity, real-time systems, protocols [15, 4].

A *d-dimensional vector addition system* (*d-VASS*, or just *VASS* when the dimension d is not relevant) is a pair $V = (Q, T)$ where Q is a non empty finite set of elements called *states*, and T is a finite set of triples in $Q \times \mathbb{Z}^d \times Q$ called *transitions*. A *configuration* is a pair $(q, x) \in Q \times \mathbb{N}^d$ also denoted as $q(x)$ in the sequel, and an *action* is a vector in \mathbb{Z}^d . The semantics is defined by introducing for each transition t the binary relation \xrightarrow{t} over the configurations defined by $p(x) \xrightarrow{t} q(y)$ if $t = (p, y - x, q)$. We also associate to a word $\sigma = t_1 \dots t_k$ of transitions t_1, \dots, t_k the binary relation $\xrightarrow{\sigma}$ over the configurations defined by $p(x) \xrightarrow{\sigma} q(y)$ if there exists a sequence c_0, \dots, c_k of configurations such that:

$$p(x) = c_0 \xrightarrow{t_1} c_1 \dots \xrightarrow{t_k} c_k = q(y)$$

The reachability problem takes as input a VASS V and two configurations $c_{\text{in}}, c_{\text{out}}$ and it decides if there exists a word σ of transitions such that $c_{\text{in}} \xrightarrow{\sigma} c_{\text{out}}$. After an incomplete proof by Sacerdote and Tenney [14], decidability of the problem was established by Mayr [11, 12], whose proof was then simplified by Kosaraju [7]. Building on the further refinements made by Lambert in the 1990s [8], in 2015, a first complexity upperbound of the reachability problem was provided [9] more than thirty years after the presentation of the algorithm introduced by Mayr [11, 12, 7, 8]. The upperbound given in that paper is cubic Ackermannian. This complexity is obtained by analyzing the computation complexity of the Mayr algorithm. By refining this algorithm and by introducing a new ranking function proving the termination of this refinement, an Ackermannian complexity upperbound was obtained in [10]. This paper also showed that the reachability problem in fixed dimension d is primitive recursive by bounding the length of executions thanks to the fast growing function F_{d+4} of the Grzegorzcz hierarchy.

*This research has been supported by ANR programme BraVAS (ANR-17-CE40-0028).

In this paper we provide an Ackermannian complexity lowerbound for the reachability problem for VASS. Moreover, **in fixed dimension $4d + 9$, we prove that the reachability problem is hard for the class F_d .** This version of the result is a draft one. A new version will soon be available on arXiv.

2 Fast Growing Functions

We introduce the sequence $(F_d)_{d \in \mathbb{N}}$ of functions $F_d : \mathbb{N} \rightarrow \mathbb{N}$ defined by $F_0(n) = n + 1$ for every $n \in \mathbb{N}$, and defined by induction for every $d \geq 1$ and $n \in \mathbb{N}$ by $F_d(n) = F_{d-1}^{n+1}(n)$.

Example 1. We have $F_1(n) = 2n + 1$ and $F_2(n) = 2^{n+1}(n + 1) - 1$ for every $n \in \mathbb{N}$. The function F_3 is a tower function which is not elementary. The *Ackermann function* F_ω is defined by $F_\omega(n) = F_{n+1}(n)$. This function is not primitive recursive.

We introduce the submonoid \mathcal{M}_d of $(\mathbb{N}^d \rightarrow \mathbb{N}^d, \circ)$ generated by the functions $D_{d,p}$ with $p \in \{1, \dots, d-1\}$ and $L_{d,p}$ with $p \in \{1, \dots, d-2\}$ partially defined over the vectors $v \in \mathbb{N}^d$ satisfying $v[p] \geq 1$ by the following equalities for every $1 \leq i \leq d$:

$$D_{d,p}(v)[i] = \begin{cases} v[i] - 1 & \text{if } i = p \\ 2v[i] & \text{if } i = p + 1 \\ v[i] & \text{otherwise} \end{cases} \quad L_{d,p}(v)[i] = \begin{cases} v[i] - 1 & \text{if } i = p \\ v[i]v[i+1] & \text{if } i = p + 1 \\ 1 & \text{if } i = p + 2 \\ v[i] & \text{otherwise} \end{cases}$$

Functions $D_{d,p}$ are called *doubling functions*, and functions $L_{d,p}$ are called *lifting functions*.

We denote by \geq the partial order over \mathbb{N}^d defined by $v \geq w$ if $v[i] \geq w[i]$ for every $1 \leq i \leq d$. We first prove some technical lemmas. In those lemmas, we implicitly use several times the fact that functions in \mathcal{M}_d are monotone, i.e. if v is in the definition domain of some $f \in \mathcal{M}_d$ then any $w \geq v$ is also in the definition domain of f and $f(w) \geq f(v)$. Given two vectors $v, w \in \mathbb{N}^d$, we write $v \sqsupseteq w$ if there exists $f \in \mathcal{M}_d$ such that $f(v) \geq w$. Notice that \sqsupseteq is transitive since functions in \mathcal{M}_d are monotonic. Moreover, since \mathcal{M}_d contains the identity function, we deduce that $v \geq w$ implies $v \sqsupseteq w$ for every $v, w \in \mathbb{N}^d$.

Lemma 1. *We have $(3 + k, 2, 3 + n, \dots, 3 + n) \sqsupseteq (2 + k, 3 + n, \dots, 3 + n)$ for every $d \geq 3$, and $n, k \geq 0$.*

Proof. Just observe that $L_{d,1}(3 + k, 2, 3 + n, \dots, 3 + n) = (2 + k, 6 + 2n, 1, 3 + n, \dots, 3 + n)$ and $D_{d,2}^{3+n}(2 + k, 6 + 2n, 1, 3 + n, \dots, 3 + n) = (2 + k, 3 + n, 2^{3+n}, 3 + n, \dots, 3 + n) \geq (2 + k, 3 + n, \dots, 3 + n)$. \square

Lemma 2. *We have $(3 + n, \dots, 3 + n) \sqsupseteq (2, 3 + F_d(n), \dots, 3 + F_d(n))$ for every $d \geq 2$ and every $n \geq 0$.*

Proof. We prove the lemma by induction.

The base case $d = 2$ is immediate since $D_{2,1}^{n+1}(3 + n, 3 + n) = (2, 2^{n+1}(3 + n)) \geq (2, 3 + F_2(n))$. Now, let us assume the case $d - 1$ proved for some $d \geq 3$. It follows that for every $n \geq 0$ there exists $f \in \mathcal{M}_{d-1}$ such that $f(3 + n, \dots, 3 + n) \geq (2, 3 + F_{d-1}(n), \dots, 3 + F_{d-1}(n))$. By incrementing all the indexes occurring in a decomposition of f into doubling and lifting functions, we get a function $g \in \mathcal{M}_d$ such that for every $m \geq 0$ we have $g(3 + m, 3 + n, \dots, 3 + n) \geq (3 + m, 2, 3 + F_{d-1}(n), \dots, 3 + F_{d-1}(n))$. Lemma 1 shows that $(3 + m, 2, 3 + F_{d-1}(n), \dots, 3 + F_{d-1}(n)) \sqsupseteq (2 + m, 3 + F_{d-1}(n), \dots, 3 + F_{d-1}(n))$. We have proved that $(3 + m, 3 + n, \dots, 3 + n) \sqsupseteq (2 + m, 3 + F_{d-1}(n), \dots, 3 + F_{d-1}(n))$ for every $n, m \geq 0$. By induction on m , we deduce that $(3 + m, 3 + n, \dots, 3 + n) \sqsupseteq (2, 3 + F_{d-1}^{m+1}(n), \dots, 3 + F_{d-1}^{m+1}(n))$ for every $m, n \geq 0$. In particular with $n = m$, we get $(3 + n, \dots, 3 + n) \sqsupseteq (2, 3 + F_{d-1}^{n+1}(n), \dots, 3 + F_{d-1}^{n+1}(n))$ for every $n \in \mathbb{N}$. Since $F_{d-1}^{n+1}(n) = F_d(n)$ we have proved the induction. \square

We deduce as a corollary the following lemma that will be useful in Section 8. The two previous lemmas 1 and 2 are no longer used in the sequel.

Lemma 3. *We have $(3 + n, \dots, 3 + n) \sqsupseteq (1, F_d(n), \dots, F_d(n))$ for every $d \geq 2$ and for every $n \in \mathbb{N}$.*

Proof. Lemma 2 shows that $(3 + n, \dots, 3 + n) \sqsupseteq (2, 3 + F_d(n), \dots, 3 + F_d(n))$. Since $(2, 3 + F_d(n), \dots, 3 + F_d(n)) \geq (1, F_d(n), \dots, F_d(n))$ we are done. \square

In the sequel, functions $D_{d,p}$ and $L_{d,p}$ will be implemented by programs **double** _{d,p} and **lift** _{d,p} introduced in sections 6 and 7 respectively.

3 Programs

We introduce the formal model of *Minsky programs* and its syntactic restriction called the *Petri programs* that have the same expressive power as VASS.

3.1 Basic Commands

Let \mathbf{C} be a finite set of elements called *counters*. A *configuration* is a mapping $\rho : \mathbf{C} \rightarrow \mathbb{N}$. We extend valuations over various expressions over the counters the expected way. For instance $\rho(x_1 + x_2) = \rho(x_1) + \rho(x_2)$ and $\rho(x_1, x_2) = (\rho(x_1), \rho(x_2))$. We also say that a valuation satisfies a constraint the expected way. For instance ρ satisfies x is even if $\rho(x)$ is even, and ρ satisfies $x_1 = x_2$ if $\rho(x_1) = \rho(x_2)$. The *zero configuration* is the configuration satisfying the constraint $c = 0$ for every counter c .

Given a counter c , the *increment command* of c , the *decrement command* of c , and the *test command* of c , are respectively denoted as $c += 1$, $c -= 1$, and $c ?= 0$. Those commands are called *basic commands*. We associate to every basic command **cmd** a function $\llbracket \mathbf{cmd} \rrbracket$ that maps any configuration ρ onto a set of configurations as follows:

- $\llbracket c += 1 \rrbracket(\rho) = \{\beta\}$ where β is defined by $\beta(c) = \rho(c) + 1$ and $\beta(x) = \rho(x)$ if $x \neq c$.
- $\llbracket c -= 1 \rrbracket(\rho)$ is the empty set if $\rho(c) = 0$, and it is equal to $\{\beta\}$ otherwise where β is the configuration such that $\beta(c) = \rho(c) - 1$ and $\beta(x) = \rho(x)$ for every counter $x \neq c$.
- $\llbracket c ?= 0 \rrbracket(\rho)$ is the empty set if $\rho(c) \neq 0$ and it is equal to $\{\rho\}$ otherwise.

3.2 Minsky Programs

A *Minsky program* M over a finite set \mathbf{C} of counters is a word $\mathbf{cmd}_1 \dots \mathbf{cmd}_n$ where \mathbf{cmd}_ℓ is either a basic command over \mathbf{C} , or a *goto L command* with $L \subseteq \{1, \dots, n+1\}$ and denoted as **goto** L . A *state* of M is a pair (ℓ, ρ) where $\ell \in \{1, \dots, n+1\}$ and ρ is a configuration. We define the binary relation \xRightarrow{M} over the states by $(\ell, \rho) \xRightarrow{M} (\ell', \rho')$ if $\ell \neq n+1$ and in that case:

- if \mathbf{cmd}_ℓ is the goto L command then $\ell' \in L$ and $\rho' = \rho$.
- if \mathbf{cmd}_ℓ is a basic command then $\ell' = \ell + 1$ and $\rho' \in \llbracket \mathbf{cmd}_\ell \rrbracket$.

The binary relation \xRightarrow{M}^* is the reflexive and transitive closure of \xRightarrow{M} . The binary relation \xrightarrow{M} over the configurations is defined by $\alpha \xrightarrow{M} \beta$ if $(1, \alpha) \xRightarrow{M}^* (n+1, \beta)$. In that case we say that starting from α there exists an execution of the Minsky program that leads to the final configuration β .

It will be convenient to execute in series Minsky programs. Notice that if M_1 and M_2 are two Minsky programs, the concatenation $M_1.M_2$ of the programs seen as words of commands

is not correct since the goto L commands of M_2 must be re-indexed. Formally, let us define for a Minsky program M and a natural number $n \geq 0$, the word M^{+n} obtained from M by replacing every goto L command by the goto $L + n$ command where $L + n = \{\ell + n \mid \ell \in L\}$. Given two Minsky programs M_1, M_2 , we denote by $M_1; M_2$ the Minsky program $M_1.M_2^{+|M_1|}$. Observe that $\alpha \xrightarrow{M_1; M_2} \beta$ if, and only if, there exists a configuration ρ such that $\alpha \xrightarrow{M_1} \rho \xrightarrow{M_2} \beta$. This construction is associative. Given a sequence M_1, \dots, M_k of Minsky programs, the Minsky program $M_1; \dots; M_k$ is denoted as follow:

$$\begin{array}{c} M_1 \\ \vdots \\ M_k \end{array}$$

Given a Minsky program M , we denote the Minsky program **goto** $\{2, 3 + |M|\}.M^{+1}$.**goto** $\{1\}$ in a more readable way as follows:

$$\begin{array}{c} \text{loop} \\ M \end{array}$$

Denoting by M' that Minsky program, notice that $\xrightarrow{M'}$ is the reflexive and transitive closure of \xrightarrow{M} .

We also denote by $c += k$ where $k \in \mathbb{N}$ the Minsky program $c += 1; \dots; c += 1$ that repeats k times $c += 1$. The Minsky program $c -= k$ is defined symmetrically. Similarly, $c_1, \dots, c_n ?= 0$ denotes $c_1 ?= 0; \dots; c_n ?= 0$.

The *reachability problem* for Minsky programs takes as input a Minsky program M and a final configuration β and it consists in deciding if there exists an execution of the Minsky program starting from the zero configuration that leads to the final configuration β . This problem is undecidable [13] even if the set of counters C is limited to 2 counters. When bounding the possible values of the counters along executions, the reachability problem becomes decidable and high complexity classes can be defined.

More formally, given a bound $B \in \mathbb{N}$, we say that a configuration is *B-bounded* if it satisfies the constraint $c \leq B$ for every counter c . We also say that a state (ℓ, ρ) is *B-bounded* if ρ is *B-bounded*. Given a Minsky program M , we denote by $\xrightarrow{M}_{\leq B}$ the binary relation over the *B-bounded* states defined by $(\ell, \rho) \xrightarrow{M}_{\leq B} (\ell', \rho')$ if $(\ell, \rho) \xrightarrow{M} (\ell', \rho')$. The reflexive and transitive closure of that relation is denoted as $\xrightarrow{M^*}_{\leq B}$. We introduce the binary relation $\xrightarrow{M}_{\leq B}$ over the configurations defined by $\alpha \xrightarrow{M}_{\leq B} \beta$ if $(1, \alpha) \xrightarrow{M^*}_{\leq B} (n+1, \beta)$ where $n = |M|$.

To prove that the reachability problem for VASS is hard for the class \mathbf{F}_ω , we provide a reduction from the following problem that is complete for that class [16]:

Input A Minsky program M of size n .

Return: Denoting by ρ the zero configuration:

- true if $\rho \xrightarrow{M} \rho$.
- false if we do not have $\rho \xrightarrow{M}_{\leq F_\omega(n)} \rho$.

For the fixed dimension $4d + 9$, to prove that the reachability problem for VASS is hard for the class \mathbf{F}_d we provide a reduction from the following problem that is complete for that class [16]:

Input A Minsky program M with two counters of size n .

Return: Denoting by ρ the zero configuration:

- true if $\rho \xrightarrow{M} \rho$.
- false if we do not have $\rho \xrightarrow{M}_{\leq F_d(n)} \rho$.

3.3 Petri Programs

A *Petri program* is a Minsky program such that test commands are only performed at the end. Formally, a Petri program is a Minsky program of the form $M; c_1, \dots, c_n \neq 0$ where M is a Minsky program without test commands.

As expected, the *reachability problem* for Petri programs takes as input a Petri program M and a final configuration β and it consists in deciding if there exists an execution of the Petri program starting from the zero configuration that leads to the final configuration β . The proof of the following lemma is immediate but it provides the link between the reachability problem for VASS, and the reachability problem for Petri programs.

Lemma 4. *When numbers are encoded in unary, the reachability problem for VASS and for Petri programs are interreducible in logspace. Moreover the dimension of the VASS and the number of counters of the Petri program are equal.*

4 The Good, the Bad, and the Conform

Let us fix a natural number $d \geq 1$. We are going to manipulate configurations provided by counters $x_0, \dots, x_d, b_1, \dots, b_d$ and their corresponding auxiliary counters denoted with a prime. For instance to express **loop at most v times** $\langle body \rangle$ where v is one of the counters $x_0, \dots, x_d, b_1, \dots, b_d$, we employ the auxiliary counter v' to which the value of v is transferred and then transferred back. Provided v' is zero at the start, the body is indeed performed at most v times.

```

loop
  v -= 1 ; v' += 1
loop
  v' -= 1 ; v += 1
<body>

```

We denote by X_i the expression $x_i + x'_i$ for every $0 \leq i \leq d$, and we denote by B_i the expression $b_i + b'_i$ for every $1 \leq i \leq d$. A configuration is said to be *i-good* with $i \in \{1, \dots, d\}$ if ρ satisfies the constraint $X_{i-1} = B_i X_i$. A configuration is said to be *good* if it is *i-good* for every $1 \leq i \leq d$. A *null* configuration is a good configuration satisfying $X_0 = 0$. A configuration ρ is said to be *i-bad* if it satisfies the constraint $X_{i-1} > B_i X_i$, and it is *j-good* for every $1 \leq j < i$. A configuration is said to be *bad* if it is *i-bad* for some i . A configuration is said to be *conform* if it is good or bad.

There exist configurations that are not conform. However, programs we consider in the sequel produce only conform configurations from conform configurations. Good and bad configurations will be used as follows. Our programs are non deterministic. However, we will prove that starting from a good configuration, if the program behaves the expected way it will produce a good configuration. If not, the program will produce a bad one. Moreover, starting from a bad configuration, programs will only produce bad configurations.

5 Check Program

We introduce a program **check_d** that checks if a conform configuration is good. Intuitively, starting from an initial conform configuration, it terminates successfully if, and only if the initial configuration is good. It will be convenient to introduce the program **flush v**

```

loop
  v' -= 1 ; v += 1

```

and the symmetric program **load** v

```

loop
   $v -= 1$  ;  $v' += 1$ 

```

We introduce the program **dec**₀ defined as:

```

flush  $x_0$ 
 $x_0 -= 1$ 

```

and the program **dec** _{p} for $p \in \{1, \dots, d\}$ defined by induction as the following program:

```

flush  $x_p$ 
 $x_p -= 1$ 
loop at most  $b_p$  times
  dec $p-1$ 

```

Intuitively, by executing the loops of **dec** _{p} the maximal number of times, we decrement X_p and all the X_j for $j < p$ in such a way the equality $X_{j-1} = B_j X_j$ is maintained. This idea is formalized as follows.

Lemma 5. *Let α be a configuration and $p \in \{0, \dots, d\}$. If α satisfies $X_p = 0$ the program **dec** _{p} is blocked when starting from α . So, assume that α satisfies $X_p > 0$. In that case, every configuration β reachable from α by program **dec** _{p} satisfies $\beta(x_i, b_i, x'_i, b'_i) = \alpha(x_i, b_i, x'_i, b'_i)$ for every $i > p$, and $\beta(B_i) = \alpha(B_i)$ for every $1 \leq i \leq d$. Moreover,*

- (i) *If the initial configuration α is i -good for every $1 \leq i \leq p$, then there exists an execution of **dec** _{p} that leads to a final configuration β satisfying additionally for every $0 \leq i \leq d$:*

$$\beta(X_i) = \alpha \left(\begin{cases} X_i - \prod_{i < j \leq p} B_j & \text{if } i \leq p \\ X_i & \text{otherwise} \end{cases} \right)$$

In particular β is i -good for every $1 \leq i \leq p$.

- (ii) *If the initial configuration is i -good for every $1 \leq i \leq p$ then every final configuration β that does not satisfy the previous conditions is j -bad for some $1 \leq j \leq p$.*
- (iii) *If the initial configuration is i -bad with $i \neq p+1$ then the final configurations is j -bad for some j such that $j = i$ or $1 \leq j \leq \min\{i, p\}$.*

Proof. The lemma is proved by induction on p . Just observe that an execution that leads to a configuration satisfying (i) is obtained by iterating the loops the maximal number of times. \square

The program **check** _{d} is defined as follows:

```

loop
  dec $d$ 
 $x_0, \dots, x_d, x'_1, \dots, x'_d \text{ ?} = 0$ 

```

We prove the correctness of program **check** _{d} as follows.

Lemma 6. *Program **check** _{d} successfully terminates on an initial conform configuration if, and only if, the initial configuration is good.*

Proof. Let us consider an initial good configuration α . If α satisfies $X_d > 0$, Lemma 5 shows that there exists an execution of **dec** _{d} starting from α that leads to a good configuration β such that $\beta(X_d) = \alpha(X_d) - 1$. It follows that by iterating $\alpha(X_d)$ times the loop, and by executing **dec** _{d} the right way, we obtain a final good configuration β satisfying $X_d = 0$. Since the configuration

β is good, we derive that β also satisfies $X_i = 0$ for every $0 \leq i \leq d$. It follows that the program **check_d** successfully executes the last line on β .

Now, let us consider an initial bad configuration α . Lemma 5 parts (iii) shows that every execution of **dec_d** can only produce bad configurations. It follows that before executing the last line, we have an i -bad configuration β . It follows that β satisfies $X_{i-1} > B_i X_i$ and in particular $X_{i-1} > 0$. Hence the last line cannot be executed and the program is blocked. \square

6 Doubling Program

We introduce in this section the *doubling* program **double_{d,p}** parameterized by $p \in \{1, \dots, d-1\}$ that intuitively implements doubling function $D_{d,p}$ introduced in Section 2.

The program **double_{d,p}** is defined as follows:

```

1: flush  $b_p$ 
2:  $b_p \mathrel{--} 1$ 
3: load  $x_p$ 
4:  $\vdots$ 
5: load  $x_d$ 
6: loop
7:    $x'_d \mathrel{--} 2$  ;  $x_d \mathrel{+=} 1$ 
8:   loop at most  $b_d$  times
9:    $\ddots$ 
10:   $x'_i \mathrel{--} 2$  ;  $x_i \mathrel{+=} 1$ 
11:  loop at most  $b_i$  times
12:   $\ddots$ 
13:   $x'_{p+1} \mathrel{--} 2$  ;  $x_{p+1} \mathrel{+=} 1$ 
14:  loop at most  $b_{p+1}$  times
15:    decp-1 ; decp-1
16:     $x'_p \mathrel{--} 2$  ;  $x_p \mathrel{+=} 2$ 
17: load  $b_{p+1}$ 
18: loop
19:   $b'_{p+1} \mathrel{--} 1$  ;  $b_{p+1} \mathrel{+=} 2$ 

```

We prove the correctness of **double_{d,p}** thanks to the following lemma.

Lemma 7. *For every good configuration α satisfying $B_p \geq 1$ and X_d is even, there exists an execution of program **double_{d,p}** starting from α that leads to a good configuration β satisfying $\beta(B_1, \dots, B_d) = D_{d,p}(\alpha(B_1, \dots, B_d))$ and $\beta(X_d) = \alpha(\frac{X_d}{2})$. Moreover, any other final configuration is null or bad.*

The program is blocked when started from a conform configuration satisfying $B_p = 0$. When the program starts from a bad configuration, it leads to bad configurations. When it starts from a good configuration satisfying X_d is odd, it leads to bad configurations.

Proof. Assume first that the initial configuration α is good and it satisfies the two constraints $B_p \geq 1$ and X_d is even. We consider the execution obtained by iterating loops the maximal number of times and where **dec_{p-1}** is executed the expected way. It follows that before the first execution of line 6 we have a configuration ρ such that $\rho(x'_j) = \alpha(X_j)$ and $\rho(x_j) = 0$ for every $p \leq j \leq d$.

Loop at line 6 is executed $\alpha(\frac{X_d}{2})$ times, and inside that loop, the **loop at most** b_i **times** with $p < i \leq d$ is executed exactly $\alpha(B_i)$ times. The last loop is executed $\alpha(B_p)$ times. It

follows that the final configuration β satisfies $\beta(B_1, \dots, B_d) = D_{d,p}(\alpha(B_1, \dots, B_d))$ and for every $0 \leq i \leq d$, we have:

$$\beta(X_i) = \alpha \left(\begin{cases} \frac{X_i}{2} & \text{if } i > p \\ X_i - X_p \prod_{i < j < p} B_j & \text{if } i < p \\ X_i & \text{if } i = p \end{cases} \right) \quad (1)$$

Let us now consider any other final configuration β reachable starting from the good configuration α and let us prove that β is null or bad. Observe that if one of the program **dec**_{*p*-1} is not executed the expected way (by executing the loops the maximal number of times), at some point we get a *i*-bad configuration for some $i \leq p-1$, and β is necessarily *j*-bad for some $j \leq i$. So, we can assume that program **dec**_{*p*-1} is always executed the right way. In particular the final configuration β is *i*-correct for every $i \leq p-1$.

Observe that line 15 is executed at most $\alpha(X_p)$ times thanks to the control given by line 16. If it is executed strictly less than $\alpha(X_p)$ times then $\beta(X_{p-1}) > \alpha(X_{p-1} - X_p)$. As $\beta(X_p) = \alpha(X_p)$, $\beta(B_p) = \alpha(B_p) - 1$, and α satisfies $X_{p-1} = B_p X_p$, we deduce that β satisfies $X_{p-1} > B_p X_p$ and we have proved that the final configuration β is *p*-bad. So, we can assume that line 15 is executed exactly $\alpha(X_p)$ times. The only way to do so, is by executing the **loop at most *b_i* times** exactly $\alpha(B_i)$ times. So, we can assume that all loops, except maybe the last one are executed the maximal number of times. It follows that β satisfies for every $0 \leq i \leq d$ the equality (1). Now, just observe that if the last loop is not executed $\alpha(B_{p+1})$ times, then $\beta(B_{p+1}) < 2\alpha(B_{p+1})$. It follows that if $\beta(X_{p+1}) > 0$ then β satisfies $X_p > B_{p+1} X_{p+1}$ and the configuration β is $(p+1)$ -bad. Observe that if $\beta(X_{p+1}) = 0$ then β is a null configuration.

Now assume that α is a good configuration such that X_d is odd. In that case, there is no way to execute line 15 exactly $\alpha(X_p)$ times. In fact, line 6 is executed at most $\alpha(\frac{X_d}{2})$ times, it means a strictly smaller number of times. It follows that line 15 is executed strictly less than $\alpha(\frac{X_d}{2} B_d \dots B_{p+1})$ times (notice that for the strictness we use the fact that α is positive). Since α is good, we derive $\alpha(\frac{X_d}{2} B_d \dots B_{p+1}) = \alpha(\frac{X_p}{2})$. In particular the number of times program **dec**_{*p*-1} is executed is strictly less than $2\alpha(\frac{X_p}{2}) = \alpha(X_p)$. As previously shown, in that case, the final configuration is necessarily *p*-bad.

Finally, let us consider an initial *i*-bad configuration ρ . Observe that if $i \leq p-1$ we deduce from Lemma 5 that the final configuration is *j*-bad for $j \leq p-1$. So we can assume that $i \geq p$. Lemma 5 shows that we can assume that the program **dec**_{*p*-1} is always executed the right way since otherwise the final configuration is *j*-bad for some $j \leq p-1$. So, we can assume that the program **dec**_{*p*-1} is always executed the right way.

If $i = p$ then α satisfies $X_{p-1} > B_p X_p$. Observe that the number of times program **dec**_{*p*-1} is executed is bounded by $\alpha(X_p)$ thanks to the limitation introduced by line 16. It follows that $\beta(X_{p-1}) \geq \alpha(X_{p-1} - X_p)$. Since $\beta(X_p) = \alpha(X_p)$, and $\beta(B_p) = \alpha(B_p)$ we derive that β satisfies $X_{p-1} > B_p X_p$. Therefore the final configuration is *p*-bad.

If $i > p$ then α satisfies $X_{i-1} > B_i X_i$. Notice that line 10 is executed at most $\alpha(\frac{X_i}{2})$. Hence, line 15 is executed at most $\alpha(\frac{X_i}{2} B_i \dots B_{p+1})$ which is strictly bounded by $\alpha(\frac{X_{i-1}}{2} B_{i-1} \dots B_{p+1})$. Since α is *j*-correct for every $j < i$, we deduce that α satisfies $\frac{X_{i-1}}{2} B_{i-1} \dots B_{p+1} = \frac{X_p}{2}$. Hence, line 15 is executed strictly less than $\alpha(X_p)$. As previously shown it follows that β is *p*-bad. \square

7 Lifting Program

We introduce in this section the *lifting* program **lift**_{*d,p*} indexed by a parameter $p \in \{1, \dots, d-2\}$ that intuitively implements lifting function $L_{d,p}$ introduced in Section 2.

The lifting program is using the *multiplication* program **mul**_{*p*} parameterized by $p \in \{1, \dots, d-2\}$ and defined as follows:

```

load bp+1
loop
  b'p+1 -= 1
  loop at most bp+2 times
    bp+1 += 1

```

Such a program is usually called a weak multiplier. The proof of the following lemma is immediate.

Lemma 8. *For every initial configuration α , every reachable configuration β satisfies $\beta(B_{p+2}) = \alpha(B_{p+2})$ and $\beta(B_{p+1}) \leq \alpha(B_{p+1}B_{p+2})$. Moreover, there exists a reachable one satisfying $\beta(B_{p+1}) = \alpha(B_{p+1}B_{p+2})$.*

Now, we introduce the following program **lift**_{d,p}.

```

1: flush bp
2: bp -= 1
3: load xp
4: flush bp+1
5: bp+1 -= 1
6: loop at most bp+1 times
7:   loop at most xp+1 times
8:     decp-1 ; x'p -= 1 ; xp += 1
9:   bp+1 += 1
10: mulp
11: flush bp+2
12: bp+2 -= 1
13: loop
14:   loop at most xp+2 times
15:     xp+1 -= 1 ; decp-1 ; x'p -= 1 ; xp += 1
16:   bp+2 -= 1
17: bp+2 += 1
18: load xp+1
19: loop at most xp+2 times
20:   x'p+1 -= 1 ; xp+1 += 1 ; decp-1 ; x'p -= 1 ; xp += 1

```

Lemma 9. *For every good configuration α satisfying $B_p \geq 1$, there exists an execution of **lift**_{d,p} starting from α that leads to a good configuration β satisfying $\beta(B_1, \dots, B_d) = L_{d,p}(\alpha(B_1, \dots, B_d))$ and $\beta(X_d) = \alpha(X_d)$. Moreover, any other final configuration produced by the program is null or bad.*

The program is blocked when started from a conform configuration satisfying $B_p = 0$. When the program starts from a bad configuration, it leads only to bad configurations.

Proof. Let us first consider an initial good configuration α satisfying $B_p \geq 1$. We consider an execution such that program **dec**_{p-1} is always executed the right way (see Lemma 5) and such that loops are executed the maximal number of times. We are going to explain why we get a good configuration satisfying the lemma. In fact, line 8 is executed $\alpha((B_{p+1}-1)X_{p+1}) = \alpha(X_p - X_{p+1})$, line 15 is executed $\alpha((B_{p+2}-1)X_{p+2}) = \alpha(X_{p+1} - X_{p+2})$. Let ρ be the configuration we obtain before executing line 17. It follows that $\rho(X_{p+1}) = \alpha(X_{p+1} - (X_{p+1} - X_{p+2})) = \alpha(X_{p+2})$. Hence, the line 20 is executed $\alpha(X_{p+2})$ times. It follows that the program **dec**_{p-1} is executed $\alpha((X_p - X_{p+1}) + (X_{p+1} - X_{p+2}) + (X_{p+2})) = \alpha(X_p)$ and we get a conform configuration satisfying

the lemma since β satisfies $\beta(B_1, \dots, B_d) = L_{d,p}(\alpha(B_1, \dots, B_d))$, and for every $1 \leq i \leq d$:

$$\beta(X_i) = \alpha \left(\begin{cases} X_i - X_p \prod_{i < j < p} B_j & \text{if } i < p \\ X_{i+1} & \text{if } i = p + 1 \\ X_i & \text{otherwise} \end{cases} \right) \quad (2)$$

Now, let us consider any other final configuration β that we can obtain after executing the program starting from α . If program **dec**_{p-1} is not executed the right way then Lemma 5 shows that β is j -bad for some $j \leq p - 1$. So, we can assume that **dec**_{p-1} is always executed the right way. Notice that if one of the loops (excluding **mul**_p, and the **flush** macros) are not executed the maximal number of times, we deduce from the previous paragraph that **dec**_{p-1} is executed strictly less than $\alpha((X_p - X_{p+1}) + (X_{p+1} - X_{p+2}) + (X_{p+2})) = \alpha(X_p)$. It follows that $\beta(X_{p-1}) > \alpha(X_{p-1}) - \alpha(X_p)$. Since α satisfies $X_{p-1} = B_p X_p$, and $\beta(B_p) = \alpha(B_p) - 1$, we deduce that β satisfies $X_{p-1} > B_p X_p$. Hence β is p -bad. So, we can assume that all the loops (excluding the ones of **mul**_p) are executed the maximal number of times. We deduce that β is a configuration satisfying equality (2) for every $i \leq 0 \leq d$. In particular β is j -correct for every $j \neq p + 1$, $\beta(X_p) = \alpha(X_p)$ and $\beta(X_{p+1}) = \alpha(X_{p+2})$. As α is good, we get $\alpha(X_p) = \alpha(X_{p+2} B_{p+1} B_{p+2}) = \beta(X_{p+1}) \beta(B_{p+1} B_{p+2})$. Observe that if $\beta(X_{p+1}) = 0$ then β is a null configuration and we are done. So, we can assume that $\beta(X_{p+1}) > 0$. Lemma 8 shows that if program **mul**_p is not executed the expected way, then $\beta(B_{p+1}) < \alpha(B_{p+1} B_{p+2})$. We deduce that β is $(p + 1)$ -bad.

Finally, let us consider an execution from an i -bad configuration α that leads to a final configuration β . Observe that if $i \leq p - 1$, from Lemma 5 we deduce that β is bad as well. So we can assume that $i \geq p$. From Lemma 5 we can assume that program **dec**_{p-1} is always executed the right way since otherwise β is bad. If $i = p$, then α satisfies $X_{p-1} > B_p X_p$. Notice that the number of times **dec**_{p-1} is called is limited by $\alpha(X_p)$. It follows that $\beta(X_{p-1}) \geq \alpha(X_{p-1} - X_p)$. Since $\beta(B_p) = \alpha(B_p) - 1$, $\beta(X_p) = \alpha(X_p)$, we deduce that β satisfies $X_{p-1} > B_p X_p$. Hence β is p -bad. If $i = p + 1$, then α satisfies $X_p > B_{p+1} X_{p+1}$. Notice that line 8 is executed at most $\alpha((B_{p+1} - 1) X_{p+1})$ times, and lines 15 and 20 are in total executed at most $\alpha(X_{p+1})$ times. It follows that **dec**_{p-1} is executed strictly less than $\alpha(X_p)$ times. It follows that β is p -bad. If $i = p + 2$ then α satisfies $X_{p+1} > B_{p+2} X_{p+2}$. Observe that line 8 is executed at most $\alpha((B_{p+1} - 1) X_{p+1}) = \alpha(X_p - X_{p+1})$. Moreover lines 15 and 20 are in total executed less than or equal to $\alpha(B_{p+2} X_{p+2}) < \alpha(X_{p+1})$. It follows that program **dec**_{p-1} is executed strictly less than $\alpha(X_p)$. It follows that β is p -bad as shown previously. If $i \geq p + 3$ it follows that α satisfies $X_{i-1} > B_i X_i$. Since X_{i-1}, B_i, X_i are constant, notice that β satisfies $X_{i-1} > B_i X_i$. Since α is j -correct for every $j \leq p + 2$, the behavior of the program is the same as starting from a good configuration. It follows that if the execution is not performed the right way, the configuration β is bad. If the execution is performed the right way, notice that β is j -correct for every $j < i$. As β satisfies $X_{i-1} > B_i X_i$, it follows that β is i -bad. \square

8 Ackermann Program

We are now ready to introduce a program parameterized by $n \in \mathbb{N}$ that is computing for every $\ell \in \mathbb{N}$ good configurations satisfying $B_d \geq F_d(n)$ and $X_d = \ell$.

We introduce the following initialization program **init**_{d,n} where $n \geq 0$ is any natural number:

```

1:  $b_1 \ += \ 3 + n \ \dots \ b_d \ += \ 3 + n$ 
2: loop
3:    $x_0 \ += \ (3 + n)^d \ \dots \ x_d \ += \ (3 + n)^0$ 

```

The proof of the following lemma is trivial by executing the loop ℓ times.

Lemma 10. *Program $\mathbf{init}_{d,n}$ produces only good configurations from the zero configuration. Moreover, for every $\ell \in \mathbb{N}$ it produces a good configuration satisfying $(B_1, \dots, B_d) = (3 + n, \dots, 3 + n)$ and $X_d = \ell$.*

The Ackermannian program $\mathbf{ack}_{d,n}$ is defined as follows:

```

initd,n
loop
  loop
    doubled,1
    ⋮
  loop
    doubled,d-1
  loop
    liftd,1
    ⋮
  loop
    liftd,d-2

```

Clearly, from Lemmas 7, 9, and 10, we deduce that program $\mathbf{ack}_{d,n}$ produces only conform configurations. Let us now prove that it can produce large good configurations.

Lemma 11. *For every function f in the monoid \mathcal{M}_d and for every $\ell \in \mathbb{N}$, program $\mathbf{ack}_{d,n}$ can produce a good configuration satisfying $(B_1, \dots, B_d) = f(3 + n, \dots, 3 + n)$ and $X_d = \ell$.*

Proof. We prove the lemma by induction on the number of basic functions that generates the function f . Observe that if f is the identity function, the proof is immediate. So, let us assume the lemma proved for some function f , and let us prove the lemma for $D_{d,p} \circ f$ for every $1 \leq p \leq d - 1$, and for $L_{d,p} \circ f$ for every $1 \leq p \leq d - 2$. Let $\ell \in \mathbb{N}$.

Let us first consider the case $D_{d,p} \circ f$. We let $v = f(3 + n, \dots, 3 + n)$ and $w = D_{d,p}(v)$. By induction, there exists an execution of $\mathbf{ack}_{d,n}$ that produces a good configuration α satisfying $(B_1, \dots, B_d) = v$, and $X_d = 2\ell$. Lemma 7 shows that there exists an execution of $\mathbf{double}_{d,p}$ that produces from α a good configuration β satisfying $(B_1, \dots, B_d) = w$, and $X_d = \frac{2\ell}{2}$. So we are done in that case.

Finally, let us consider the case $L_{d,p} \circ f$. We let $v = f(3 + n, \dots, 3 + n)$ and $w = L_{d,p}(v)$. By induction, there exists an execution of $\mathbf{ack}_{d,n}$ that produces a good configuration α satisfying $(B_1, \dots, B_d) = v$, and $X_d = \ell$. Lemma 9 shows that there exists an execution of $\mathbf{lift}_{d,p}$ that produces from α a good configuration β satisfying $(B_1, \dots, B_d) = w$, and $X_d = \ell$. So we are done also in that case.

We have proved the lemma by induction. □

We deduce the following lemma.

Lemma 12. *For every $\ell \in \mathbb{N}$ and $d \geq 2$, program $\mathbf{ack}_{d,n}$ can produce a good configuration satisfying $B_d \geq F_d(n)$ and $X_d = \ell$.*

Proof. Lemma 3 shows that there exists a function $f \in \mathcal{M}_d$ such that $f(3 + n, \dots, 3 + n) \geq (1, F_d(n), \dots, F_d(n))$. Now, just apply Lemma 11 with f . □

9 Ackermannian Weak Amplifier

In [2] we introduced the notion of B -amplifier defined as a Petri program that produces when it successfully terminates configurations satisfying $\mathbf{b} = B$ and $\mathbf{y} = \mathbf{b}\mathbf{x}$ for some counters $\mathbf{y}, \mathbf{b}, \mathbf{x}$.

Such an amplifier is then used for simulating Minsky programs with counters bounded by B . In this section, we introduce a similar notion called weak Amplifiers.

A *weak amplifier* is a Petri program that contains the counters y, b, x and such that every configuration reached by a successful execution from the zero configuration satisfies $y = bx$ and $c = 0$ for every counter $c \notin \{y, b, x\}$. A *weak amplifier* is said to be B -strong for some $B \in \mathbb{N}$ if for every $\ell \in \mathbb{N}$, there exists a successful execution from the zero configuration that leads to a configuration satisfying $b \geq B$ and $x = \ell$.

We now provide a weak amplifier that is $F_d(n)$ -strong. In order to obtain that Petri program, we first slightly modify $\mathbf{ack}_{d,n}$ by adding three counters y, b, x that intuitively simulate X_{d-1}, B_d, X_d . More formally, after every command $x_{d-1} += 1$ or $x'_{d-1} += 1$ in $\mathbf{ack}_{d,n}$ we insert the command $y += 1$, after every command $x_{d-1} -= 1$ or $x'_{d-1} -= 1$ in $\mathbf{ack}_{d,n}$ we insert the command $y -= 1$, and so one for b and x . We denote by $\mathbf{ack}'_{d,n}$ the program we obtain that way. We now introduce the program $\mathbf{amp}_{d,n}$ defined as follows:

```

ack'd,n
loop
  decd
loop
  b1  $-= 1$ 
loop
  b'1  $-= 1$ 
   $\vdots$ 
loop
  bd  $-= 1$ 
loop
  b'd  $-= 1$ 
x0, ..., xd, x'0, ..., x'd, b1, ..., bd, b'1, ..., b'd  $?= 0$ 

```

Lemma 13. *Program $\mathbf{amp}_{d,n}$ is a $F_d(n)$ -strong weak amplifier.*

Proof. Notice that $\mathbf{amp}_{d,n}$ is a Petri program. Moreover every final configurations starting from the zero configuration satisfies $c = 0$ for every counter $c \notin \{y, b, x\}$.

Let us consider an execution of the program that successfully computes a configuration β from the zero configuration. Let α be the configuration we obtain just after $\mathbf{ack}'_{d,n}$. Lemma 12 shows that α is a conform configuration. Let β' be the configuration just after execution the first loop. Since the remainder of the program do not modify the counters $x_0, \dots, x_d, x'_0, \dots, x'_d$. We deduce that β' can execute the command $x_0, \dots, x_d, x'_0, \dots, x'_d ?= 0$ since β successfully executed it. It follows that there exists an execution of the program \mathbf{check}_d from α to β' . From Lemma 6 we deduce that α is good. In particular α satisfies $X_{d-1} = B_d X_d$. By construction notice that α also satisfies $y = X_{d-1}$, $b = B_d$ and $x = X_d$. It follows that α satisfies $y = bx$. We have proved that $\mathbf{amp}_{d,n}$ is a weak amplifier.

Now, let us prove that it is $F_d(n)$ -strong. Let $\ell \in \mathbb{N}$. Lemma 12 shows that there exists an execution of $\mathbf{ack}_{d,n}$ that leads to a good configuration satisfying $B_d \geq F_d(n)$ and $X_d = \ell$. By simulating that execution in $\mathbf{ack}'_{d,n}$ we get a good configuration α satisfying $b \geq F_d(n)$ and $x = \ell$. Since α is good, Lemma 6 shows that there exists an execution of \mathbf{check}_d starting from α that leads to a configuration β' . Denoting by β the configuration we obtain from β' by replacing the valuation of the counters $\{b_1, \dots, b_d, b'_1, \dots, b'_d\}$ by zero, observe that we have proved that there exists an execution of $\mathbf{amp}_{d,n}$ from the zero configuration to β . Since β and α coincides on y, b, x we deduce that $b \geq F_d(n)$ and $x = \ell$. We have proved the lemma. \square

10 Simulating Tests

We now provide a Petri program $W \triangleright M$ that simulates thanks to a B -strong weak amplifier W , a Minsky program M with counters bounded by a value at least as large as B . The construction is exactly the same as the one given in [2]. Properties satisfied by the construction, starting from a weak amplifier, and not a strong one as in [2] are new.

Under the stated assumptions, we now define a construction of the Petri program $W \triangleright M$. The idea is to turn each counter c of M into one through supplementing it by a new counter c' and ensuring that the invariant $c + c' = R$ for some large natural number R is maintained, so that a test command of c can be replaced by loops that R times increment c and then R times decrement c . Counter b provided by W is employed to initialise each complement counter c' , whereas x and y are used to ensure that if y is zero at the end of the run then all the loops in the simulations of the tests iterated R times as required. Concretely, assume that $W = W'; x_1, \dots, x_n \text{ ?} = 0$ where W' is a Petri program without test command, the program $W \triangleright M$ is constructed as follows:

- (i) counters are renamed if necessary so that no counter occurs in both W and M ;
- (ii) letting c_1, \dots, c_l be the counters of M , new counters c'_1, \dots, c'_l are introduced and the following code is inserted at the beginning of M :

```

loop
   $c'_1 \text{ += } 1 \ ; \ \dots \ ; \ c'_l \text{ += } 1$ 
   $b \text{ -= } 1 \ ; \ y \text{ -= } 1$ 
 $x \text{ -= } 1$ 

```

(we shall show that executions necessarily iterate this loop R times, i.e. until counter b becomes zero);

- (iii) every $c_i \text{ += } 1$ command in M is replaced by

```

 $c_i \text{ += } 1 \ ; \ c'_i \text{ -= } 1;$ 

```

- (iv) every $c_i \text{ -= } 1$ command in M is replaced by

```

 $c_i \text{ -= } 1 \ ; \ c'_i \text{ += } 1;$ 

```

- (v) every $c_i \text{ ?} = 0$ command in M is replaced by

```

loop
   $c_i \text{ += } 1 \ ; \ c'_i \text{ -= } 1$ 
   $y \text{ -= } 1$ 
 $x \text{ -= } 1$ 
loop
   $c'_i \text{ -= } 1 \ ; \ c_i \text{ += } 1$ 
   $y \text{ -= } 1$ 
 $x \text{ -= } 1$ 

```

(we shall show that complete runs necessarily iterate each of the two loops R times, i.e. they check that c_i equals 0 through checking that c'_i equals R by transferring R from c'_i to c_i and then back);

- (vi) the Petri program $W \triangleright M$ is defined as $W'; M'; x_1, \dots, x_n, y \text{ ?} = 0$ where M' is the program M modified as stated.

We remark that simulating test commands of counters bounded by some R using transfers from and to their complements is a well-known technique that can be found already in Lipton [1]; the novelty here is the cumulative verification of such simulations, through decreasing appropriately the two counters y and x whose ratio is R , and checking that y is zero finally.

10.1 Correctness

Correctness. The next proposition states that the construction of $W \triangleright M$ is correct. In one direction, the proof proceeds by observing that $W \triangleright M$ can simulate faithfully any execution of M . In the other direction we argue that although some of the loops introduced in steps (v) may iterate fewer than R times and hence erroneously validate a test, the ways in which counters x and y are set up by W and used in the construction ensure that no such run can continue to a complete one. Informally, as soon as a loop in a simulation of a test iterates fewer than R times, the equality $y = x \cdot R$ turns into the strict inequality $y > x \cdot R$ which remains for the rest of the run, preventing counter y from reaching zero.

Proposition 14. *Let α be the zero configuration, β be any configuration, and assume that W is B -strong.*

- If $\alpha \xrightarrow{M}_{\leq B} \beta$ then $\alpha \xrightarrow{W \triangleright M} \beta$.
- If $\alpha \xrightarrow{W \triangleright M} \beta$ then $\alpha \xrightarrow{M} \beta$.

Proof. The first item is straightforward: from an execution of M with counters bounded by B , let ℓ be the number of test commands performed along the execution, we obtain an execution of $W \triangleright M$ with the same final valuation of counters by

- running W to terminate with a configuration satisfying $b \geq B$, $x = 2\ell + 1$, $y = x \cdot b$ and all the other counters are equal to 0, where the latter counters will remain untouched for the rest of the run and hence satisfy the requirement to be zero finally (cf. step (vi) of the construction), let R be the valuation of b at that point,
- iterating the loop in step (ii) R times to initialise each complement counter c'_i to R , which also subtracts R and 1 from y and x (respectively) as well as decreases y to 0, and
- in place of every test command in M , iterating both loops in step (v) R times, which subtracts $2R$ and 2 from y and x (again respectively), eventually decreasing them both to 0.

For the second item, consider an execution of $W \triangleright M$ from the zero configuration to a configuration β . We let ρ be the configuration we obtain just after executing W' . Firstly, by step (vi) and the fact that counters y_1, \dots, y_m are not used after executing the part of code from W , we have that ρ satisfies $y = bx$. Let us introduce $R = \rho(b)$. Extracting an execution of M with the same final configuration β is easy once we show that, for each simulation of a $c_i \neq 0$ command by the code in step (v) of the construction, the values of c_i at the start and at the finish of the code are 0.

After the code in step (ii) we therefore have that $c_i + c'_i \leq R$ for all i . We infer that

$$x_i + x'_i \leq R \text{ for all } i, \text{ and } y \geq x \cdot R$$

is an invariant that is maintained by the rest of the run.

Now, due to step (vi) again, y is zero finally, and so the inequality $y \geq x \cdot R$ is finally an equality. Therefore, x is zero finally as well. Arguing backwards through the execution, we conclude that in fact $y = x \cdot R$ has been maintained and that, for each simulation of a $x_i \neq 0$ command, each of the two loops has been iterated exactly R times, and hence the values of c_i at its start and at its finish have been as required. Also, the loop introduced in step (ii) has been iterated R times, and b is zero finally. \square

11 Conclusion

By applying Proposition 14 with the Ackermannian weak amplifier, we deduce the following complexity result.

Theorem 15. *The vector addition system with states reachability problem is hard for ACKERMANN. Moreover, in fixed dimension $4d + 9$ the reachability problem is F_d -hard.*

Proof. Just observe that $\mathbf{amp}_{n+1,n}$ is a weak amplifier that is $F_{n+1}(n)$ -strong. Since $F_{n+1}(n) = F_\omega(n)$, by applying Proposition 14 we deduce that the reachability problem is hard for ACKERMANN.

For the fix dimension, just observe that we just need to simulate Minsky machines M with two counters. In total, the weak amplifier $\mathbf{amp}_{d,n} \triangleright M$ is using 4 counters for the Minsky machine, $4d + 1$ counters corresponding to $(x_i)_{0 \leq i \leq d}$, $(b_i)_{1 \leq i \leq d}$, $(x'_i)_{1 \leq i \leq d}$, $(b'_i)_{1 \leq i \leq d}$ (since we do not use x'_0), the three counters y, b, x , and the auxiliary counter b' (we do not need auxiliary counters for x and y in the construction). So, in total, we have $4 + 4d + 1 + 3 + 1 = 4d + 9$ counters. \square

It follows that the complexity of the reachability problem is closed since additionally, we have the following result.

Theorem 16 ([10]). *The vector addition system with states reachability problem is easy for ACKERMANN. Moreover, in fixed dimension d the reachability problem is F_{d+4} -easy.*

Notice that in fixed dimension $4d + 9$ we still have a gap between F_d and F_{4d+13} .
