Abstract. For an ω -word language L , the derived tree language $\text{Path}(L)$ is the language of trees having all their paths in L . We consider the hierarchies of deterministic automata on words and nondeterministic automata on trees with Rabin conditions in chain form. **We show that L is on some level of the hierarchy of deterministic word automata iff $\text{Path}(L)$ is on the same level of the hierarchy of nondeterministic tree automata.**

1 Introduction

For an ω -regular set of infinite words $L \subseteq \Sigma^\omega$, we consider the *derived language* of infinite binary trees, $\text{Path}(L)$, consisting of the trees all of whose paths are in L . In this paper, we address the following question: what is the connection between the complexity of L and that of $\text{Path}(L)$? Here, by the complexity of a language of ω -words or trees we understand the minimal complexity (in appropriate sense) of an automaton recognizing this language.

One motivation for considering this question is the following. In application of automata to program verification, a language L usually represents some property of computations of a program, e.g. expressed in a temporal logic of linear time. Now, we are often interested in a more general issue of whether all computations of a program satisfy the given property. Representing all possible computations of a program by a tree we are led to consider the derived tree language $\text{Path}(L)$.

In most of the cases our language L will be an ω -regular language. It is easy to transform a deterministic automaton recognising L into a *deterministic* automaton recognising $\text{Path}(L)$. However, we may a priori hope that using nondeterminism in some clever way we can simplify the automaton for $\text{Path}(L)$.

In [6], Kupferman, Safra and Vardi investigated this question and showed a result that refutes such a hope in a special case of Büchi automata. More specifically, these authors show that a derived tree language is recognizable by a *nondeterministic* Büchi tree automaton if and only if the original language of ω -words is recognizable by a *deterministic* Büchi automaton. Read under the negation, the implication “only if” says that nondeterministic Büchi tree automata do not recognize more languages of the form $\text{Path}(L)$ than they must. In yet other words, if an ω -regular language L cannot be recognized by a deterministic Büchi automaton, its inherent difficulty persists in $\text{Path}(L)$.

* Supported by Polish KBN grant No. 8 T11C 002 11

In the present paper we show that a similar phenomenon occurs for *all* ω -regular languages. To make the statement precise, we need somehow to measure the complexity of languages L and $\text{Path}(L)$. This can be done using hierarchies classifying ω -regular languages of trees or words. Our choice here (advocated below) is to consider the hierarchies induced by an index of a Mostowski acceptance condition. This condition, in different phrasing, was introduced by A.W. Mostowski [7]. It was independently introduced by Emerson and Jutla [3]. We use their formulation of the condition.

The Mostowski condition is given by a function $\Omega : Q \rightarrow \mathbb{N}$ assigning to each state of the automaton a natural number called its *priority*. Then a computation path is accepting if $\limsup_{n \rightarrow \infty}$ of all the priorities occurring along the path is even, in other words, the highest priority persisting infinitely often is even. The index of a condition $\Omega : Q \rightarrow \mathbb{N}$ is the pair (ι, n) where ι and n are, respectively, the minimal and maximal values of the function Ω . By the nature of Mostowski condition, one can always scale Ω down so that ι is either 0 or 1. The concept of an index naturally gives rise to the hierarchies of ω -regular languages of words and trees recognized by automata equipped with Mostowski condition. Here we shall focus on the hierarchies induced by *deterministic* automata on ω -words and *nondeterministic* automata on trees. Both hierarchies are known to be infinite and to exhaust the classes of ω -regular languages and regular sets of infinite trees, respectively. Moreover, these hierarchies refine the analogous hierarchies induced by the Rabin acceptance criterion. (Note that **a hierarchy of nondeterministic automata on ω -words is uninteresting as it collapses at the level of Büchi automata**, i.e., automata of the Mostowski index $(1, 2)$.)

Our main result is that **$\text{Path}(L)$ can be recognized by a nondeterministic tree automaton of Mostowski index (ι, n) iff L can be recognized by a deterministic automaton of the same index**. That is, L and $\text{Path}(L)$ are on the same level in the corresponding hierarchies. In [6] the result was shown for index $(1, 2)$.

Let us comment on the advantages of the Mostowski criterion compared to other acceptance criteria considered in the literature, and on the relevance of the aforementioned hierarchies.

The Mostowski condition is as powerful as Muller condition for nondeterministic automata on trees [7] and deterministic automata on ω -words [16]. Yet, Mostowski condition is much easier to work with. This is mainly because this is the unique condition that admits memoryless winning strategies for both of the players in infinite games with perfect information. This fact allows for a relatively easy proof of Rabin's Complementation Lemma ([8], cf. [14]); it is also used in many other applications of automata. The other reason for considering Mostowski condition is that when translating the μ -calculus into automata one naturally ends up with automata with Mostowski condition [3, 4]. Finally, as we have mentioned above, the hierarchies induced by the Mostowski condition are more subtle than those induced by the Rabin condition (cf. [11]); they also enjoy nice symmetry.

The aforementioned hierarchies are interesting for at least two reasons. First, they allow to classify the expressive power of formalisms. For example, one can

better understand the expressive power of some logic of programs by translating it into automata of some level of the hierarchy. The second reason comes from considering complexity problems. For example, the general framework for solving satisfiability problems for logics of programs is to translate them into automata and then to do the emptiness check. Up to current knowledge, the deterministic complexity of the emptiness check depends exponentially on the size of the index (in general it is NP-complete for Rabin automata [2] and in $\text{NP} \cap \text{co-NP}$ for Mostowski automata [1]).

Our work was directly inspired by the work of Kupferman, Safra and Vardi [6], but our proof is different from theirs. For our proof we need a characterization of the index of an ω -word language in terms of properties of the graph of a deterministic automaton recognizing the language. This is related with the work of Wagner [16]. One may see our characterization as a simplification of his characterization for the restricted case of Mostowski conditions. Actually **our characterization of Mostowski index can be transformed into a polynomial time algorithm computing the index of an ω -regular language** (i.e. a minimal index of an automaton recognizing L). This is related with the work of Krishnan, Puri and Brayton [5] who show that computing the Rabin index of a language presented by a deterministic Rabin automaton is NP-complete. On the other hand, solving the same question is polynomial if the winning condition of the automaton is given in Muller form (c.f. Wilke and Yoo [17]).

The plan of the paper is as follows. We start with the preliminary section introducing automata and the hierarchies. In Section 3, we show a simple characterization of the index of a ω -language in terms of properties of the graph of a deterministic Mostowski automaton recognizing the language. In the final section we use this characterization to show the main theorem.

2 Preliminaries

The set of natural numbers is denoted by ω or by \mathbb{N} . For a set X , X^* is the set of finite words over X , including the empty word ε , and X^ω is the set of mappings from ω to X usually referred to as *infinite words*. The *length* of a finite word w is denoted by $|w|$; note that $|\varepsilon| = 0$. We write $v \leq w$ to mean that v is an *initial segment* of w . For $u \in X^\omega$, we let $\text{Inf}(u) = \{x \in X : (\forall m \exists n > m) u(n) = x\}$ be the set of elements appearing infinitely often in u .

A nonempty subset T of X^* closed under initial segments is called a *tree*. The elements of T are called *nodes*, the \leq -maximal nodes are *leaves* and ε is the *root* of T . If $u \in T$, $x \in X$, and $ux \in T$ then ux is an *immediate successor* of u in T . An infinite sequence $P = (w_0, w_1, \dots)$ such that $w_0 = \varepsilon$ and, for each m , w_{m+1} is an immediate successor of w_m is called a *path* in T .

If Σ is an arbitrary set and T is a tree then a mapping $t : T \rightarrow \Sigma$ is called an Σ -valued tree or shortly a Σ -tree; in this context T is the *domain* of t denoted by $T = \text{dom}(t)$. We say “root of t ”, “path in t ” etc., referring to the corresponding objects in $\text{dom}(t)$. If $P = (w_0, w_1, \dots)$ is a path in t , we denote by $t(P)$ the

labeling of P , i.e., the ω -word $t(w_0)t(w_1)\dots$ in Σ^ω . Note that $\text{Inf}(t(P))$ is the set of values occurring infinitely often on the path P .

We now fix a finite alphabet Σ . For notational convenience, we shall focus in this paper on full binary trees over Σ , i.e., the Σ -trees with $\text{dom}(t) = \{1, 2\}^*$. Thus, every node $w \in \text{dom}(t)$ has exactly two successors $w1$ and $w2$. Let T_Σ be the collection of all such trees.

Lemma 1. *The following is the key concept of our paper.*

Definition 2. Let $L \subseteq \Sigma^\omega$. The *path tree language derived from L* is defined by

$$\text{Path}(L) = \{t \in T_\Sigma : \text{for each path } P \text{ in } t, t(P) \in L\}$$

We call a set $M \subseteq T_\Sigma$ a *path tree language* whenever $M = \text{Path}(L)$, for some $L \subseteq \Sigma^\omega$.

Examples. Let $\Sigma = \{a, b\}$, and let $L_1 = \{a, b\}^*a^\omega$, $L_2 = (\{a, b\}^*b)^\omega$ (for simplicity we abbreviate $\{s\}$ by s). Then $\text{Path}(L_1)$ is the set of trees such that on each path, b occurs only finitely many times, while $\text{Path}(L_2)$ is the set of trees such that on each path b occurs infinitely often.

Not every set of trees is a path language. For example, the set of trees t , such that $t(w) = a$ for at least one w , is not.

Automata on words A finite automaton on infinite words can be presented as a tuple $\mathcal{A} = \langle \Sigma, Q, q_0, Tr, Acc \rangle$, where Σ is a finite alphabet, Q is a finite set of *states*, q_0 is an *initial state*, $Tr \subseteq Q \times \Sigma \times Q$ is a set of *transitions*, and $Acc \subseteq Q^\omega$ is an acceptance criterion, usually given in some special finitary form.

A *run* of the automaton \mathcal{A} on an infinite word $u \in \Sigma^\omega$ can be presented as an infinite word $r \in Q^\omega$ such that $r(0) = q_0$, and $\langle r(m), u(m), r(m+1) \rangle \in Tr$ for every $m < \omega$. A run is *accepting* if it belongs to Acc . A word $u \in \Sigma^\omega$ is *accepted* by \mathcal{A} if there exists an accepting run of \mathcal{A} on u . The set of all accepted words is denoted $L(\mathcal{A})$.

An automaton \mathcal{A} as above is *deterministic* whenever Tr is a partial function from $Q \times \Sigma$ to Q , i.e., for every $q \in Q$, $\sigma \in \Sigma$, there is at most one q' such that $\langle q, \sigma, q' \rangle \in Tr$. Note that a deterministic automaton can have at most one run on a given word $u \in \Sigma^\omega$.

Several kinds of automata have been considered in the literature according to the actual form of the acceptance criterion. A *Büchi criterion* is given by a set $F \subseteq Q$, and the corresponding set Acc consists of those r for which $\text{Inf}(r) \cap F \neq \emptyset$. A *Muller criterion* is given by a family $\mathcal{F} \subseteq \wp(Q)$, and $Acc = \{r : \text{Inf}(r) \in \mathcal{F}\}$. A *Rabin criterion* is given by family $\{(L_1, U_1), \dots, (L_n, U_n)\}$, $L_i, U_i \subseteq Q$, and $Acc = \{r : (\exists i) \text{Inf}(r) \cap L_i = \emptyset \text{ and } \text{Inf}(r) \cap U_i \neq \emptyset\}$. Note that Büchi criterion can be presented as a special case of Rabin criterion (namely, $\{\emptyset, F\}$), and the last as a special case of Muller criterion.

In this paper we focus on yet another criterion that we call the *Mostowski acceptance criterion*. (This criterion has been often referred to as Rabin criterion

in chain form.) Mostowski criterion can be presented by a *priority function* $\Omega : Q \rightarrow \mathbb{N}$, and Acc consists of those r for which $\limsup_{n \rightarrow \infty} \Omega(r(n))$ is *even*; in other words, the highest priority repeating infinitely often is even. It is not difficult to see that this can be represented by a Rabin criterion given by a family $(\{q : \Omega(q) \text{ is odd and } \geq i+1\}, \{q : \Omega(q) \text{ is even and } \geq i\})$, where i ranges over even numbers less than or equal to $\max(\Omega(Q))$.

According to the actual form of the acceptance criterion we shall refer to Büchi automata, Mostowski automata, etc.

Two automata $\mathcal{A}_1, \mathcal{A}_2$ are *equivalent* whenever $L(\mathcal{A}_1) = L(\mathcal{A}_2)$. By the remarks above, for every Büchi, Rabin or Mostowski automaton, there is an equivalent Muller automaton.

Moreover, the following facts are well-known (see e.g. [13]).

Theorem 3. *For every Muller automaton there is an equivalent nondeterministic Büchi automaton, and an equivalent deterministic Mostowski automaton, but in general there may be no equivalent deterministic Büchi automaton.*

Automata on trees An automaton over binary trees can be presented by $\mathcal{A} = \langle \Sigma, Q, q_0, Tr, Acc \rangle$, where all the items are as for automata on words except that $Tr \subseteq Q \times \Sigma \times Q \times Q$. A *run* of \mathcal{A} on a tree $t \in T_\Sigma$ is a Q -valued tree $r : \{1, 2\}^* \rightarrow Q$ such that $r(\varepsilon) = q_0$, and, for each $w \in \text{dom}(r)$, the tuple $\langle r(w), t(w), r(w1), r(w2) \rangle$ is in Tr .

A path P in a run r is *accepting* if $r(P) \in Acc$; a run is accepting if so are all of its paths. The set of trees *accepted* by \mathcal{A} , denoted $L(\mathcal{A})$, consists of those $t \in T_\Sigma$ for which there exists an accepting run of \mathcal{A} on t .

Two automata $\mathcal{A}_1, \mathcal{A}_2$ are *semantically equivalent* whenever $L(\mathcal{A}_1) = L(\mathcal{A}_2)$.

Similarly as for automata on infinite words, we can consider different kinds of tree automata according to the form of the acceptance criterion. Since the concept of acceptance criterion is the same as for automata on words, we have again some trivial inclusions. Moreover, Mostowski [7] established the following.

Theorem 4. *For every Muller tree automaton there is an equivalent Mostowski tree automaton.*

This is the furthest that the analogy with Theorem 3 can go. In contrast to automata on words, **tree automata cannot in general be determinized and the expressive power of nondeterministic Büchi tree automata is weaker than that of Muller automata, and incomparable with that of deterministic Muller tree automata** [12].

2.1 Index hierarchies

It is an acceptance criterion that gives rise to the expressive power of automata; the criteria also induce several semantical hierarchies. Here we will restrict our considerations to the hierarchy of Mostowski conditions because there is close correlation between this hierarchy and both: the hierarchy of Rabin conditions and the hierarchy of fixpoint alternations (cf. [11]).

Definition 5. An *index* of a Mostowski condition given by the function Ω is a pair (ι, n) , where ι and n are the minimal and the maximal values of Ω , respectively.

We say that a language $L \subseteq \Sigma^\omega$ is *ι - n -feasible* if L can be recognized by a *deterministic Mostowski automaton* with the condition of index (ι, n) . Otherwise, L is *ι - n -unfeasible*.

We say that a set of *trees* $M \subseteq T_\Sigma$ is *ι - n -feasible* if it can be recognized by a *nondeterministic Mostowski automaton on trees* with the condition of index (ι, n) , and is *ι - n -unfeasible* otherwise.

Note that we express feasibility of sets of words in terms of deterministic automata, and feasibility of sets of trees in terms of general, i.e., nondeterministic automata.

It turns out that the hierarchy of indices induces a strict hierarchy of languages. Let, for $n < \omega$, $\Sigma_n = \{0, 1, \dots, n\}$. Consider the following families of languages, $M_n, N_n \subseteq \Sigma_n^\omega$:

$$M_n = \{u \in \Sigma_n^\omega : \limsup_{i \rightarrow \infty} u(i) \text{ is even} \}$$

$$N_n = \{u \in \Sigma_n^\omega : \limsup_{i \rightarrow \infty} u(i) \text{ is odd} \}$$

The following results have been originally stated in different terms but the actual phrasing follows directly from the correspondence between Rabin and Mostowski indices (cf. [11]).

Theorem 6 (Wagner [15]). *For every $n < \omega$: (i) M_n is 0- n -feasible but 1- $(n+1)$ -unfeasible; (ii) N_n is 1- $(n+1)$ -feasible but 0- n -unfeasible.*

Theorem 7 (Niwiński [9, 11]). *For every $n < \omega$: (i) $\text{Path}(M_n)$ is 0- n -feasible but 1- $(n+1)$ -unfeasible; (ii) $\text{Path}(N_n)$ is 1- $(n+1)$ -feasible but 0- n -unfeasible.*

We end this section by an observation which is an easy part of our main result.

Proposition 8. *For a deterministic Mostowski automaton \mathcal{A} , $\text{Path}(L(\mathcal{A}))$ is recognized by a (deterministic) Mostowski tree automaton of the same index.*

Proof. If $\mathcal{A} = \langle \Sigma, Q, q_0, Tr, Acc \rangle$ is a deterministic automaton recognizing L , then the automaton for $\text{Path}(L)$ is $\mathcal{A}' = \langle \Sigma, Q, q_0, Tr', Acc \rangle$, with all the same components as \mathcal{A} but $Tr' = \{\langle q, a, q', q' \rangle : \langle q, a, q' \rangle \in Tr\}$. \square

3 Flower Lemma

In this section we will show a connection between the Mostowski index of an ω -word language and the shape of a deterministic Mostowski automaton recognizing the language. Roughly speaking, we will show that in the graph of an automaton recognizing a “hard” language there must be a subgraph, called a flower, “responsible” for this hardness.

Definition 9. Let $\mathcal{A} = \langle \Sigma, Q, q_0, Tr, \Omega \rangle$ be a Mostowski automaton on words. The *graph* of \mathcal{A} is the graph obtained by taking Q as the set of vertices and adding an edge from q to q' whenever $\langle q, a, q' \rangle \in Tr$, for some letter a .

A *path* in a graph is a sequence of vertices v_1, \dots, v_j , such that, for every $i = 1, \dots, j-1$ there is an edge from v_i to v_{i+1} in the graph. A *maximal strongly connected component* of a graph is a maximal subset of vertices of the graph, such that, for every two vertices v_1, v_2 in the subset, there is a path from v_1 to v_2 and from v_2 to v_1 .

For an integer k , a *k-loop* in \mathcal{A} is a path v_1, \dots, v_j in the graph of \mathcal{A} such that, $v_1 = v_j$, $j > 1$ and $k = \max\{\Omega(v_i) : i = 1, \dots, j\}$. Please observe that a *k-loop* must necessarily go through at least one edge.

Given integers m and n , a state $q \in Q$ is an *m-n-flower* in \mathcal{A} if for every $k \in \{m, \dots, n\}$ there is, in the graph of \mathcal{A} , a *k-loop* containing q .

First, we need an operation allowing us to scale unnecessary indices up.

Definition 10. For a Mostowski automaton \mathcal{A} as above and an integer i we define the automaton $\mathcal{A} \uparrow^i$ obtained from \mathcal{A} by *lifting the index i* . The automaton $\mathcal{A} \uparrow^i$ has all the same components as \mathcal{A} except for the priority function $\Omega \uparrow^i$ defined in the following steps:

1. Take the set $Q_{\leq i} = \{q \in Q : \Omega(q) \leq i\}$. Let $G_{\leq i}$ denote the graph of \mathcal{A} restricted to the states from $Q_{\leq i}$.
2. If S is a trivial maximal strongly connected component of the graph $G_{\leq i}$, i.e., a component consisting of one state without a self loop, then let $\Omega \uparrow^i(q) = i + 1$ for q being the unique state in S .
3. If S is a nontrivial maximal strongly connected component of $G_{\leq i}$ and S contains only states of priorities strictly smaller than i then let $\Omega \uparrow^i(q) = \Omega(q) + 2$ for every $q \in S$.
4. If a state q is in none of the above components then let $\Omega \uparrow^i(q) = \Omega(q)$.

Lemma 11. For every deterministic Mostowski automaton \mathcal{A} on words and every integer i : $L(\mathcal{A}) = L(\mathcal{A} \uparrow^i)$.

Proof. Let $\mathcal{A} = \langle \Sigma, Q, q_0, Tr, \Omega : Q \rightarrow \{0, \dots, n\} \rangle$ be a deterministic Mostowski automaton on words. Consider an infinite word $w \in \Sigma^\omega$. There is at most one run of \mathcal{A} on w and if it exists it is also a run of $\mathcal{A} \uparrow^i$. This run determines the set of states Q_w that are met infinitely often on the run. Let $k = \max\{\Omega(q) : q \in Q_w\}$.

Suppose $k > i$. Every state of priority k in Q_w has still the priority k in $\mathcal{A} \uparrow^i$. Observe that if $\Omega \uparrow^i(q) \neq \Omega(q)$ then $\Omega \uparrow^i(q) \leq i + 1$. Hence $k = \max\{\Omega \uparrow^i(q) : q \in Q_w\}$ as well. So, in this case, \mathcal{A} accepts w iff $\mathcal{A} \uparrow^i$ does.

If $k \leq i$ then all the states in Q_w belong to the same strongly connected component of the graph $G_{\leq i}$. According to the definition of $\mathcal{A} \uparrow^i$, all of the priorities of the states in Q_w are either increased by 2 or left unchanged. In both cases, \mathcal{A} accepts w iff $\mathcal{A} \uparrow^i$ does. \square

Lemma 12. Let \mathcal{A} be a deterministic Mostowski automaton and let $i \in \mathbb{N}$. Let $\mathcal{B} = \mathcal{A} \uparrow^{0 \uparrow^1} \dots \uparrow^i$. If a state q has priority m in \mathcal{B} then q is a *m-i-flower* in \mathcal{B} .

Proof. We prove the claim by induction on i . Let us denote by $\Omega_{\leq i}$ the priority function of the automaton $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^i$.

First, consider the case $i = 0$. If $\Omega_{\leq 0}(q) > 0$ then the claim is trivial, so suppose $\Omega_{\leq 0}(q) = 0$.

Let, as in Definition 10, $G_{\leq 0}$ be the graph of \mathcal{A} restricted to the states that have priority 0. There must be a 0-loop in $G_{\leq 0}$ containing q , otherwise the priority of q would be increased. Call this loop P . Clearly, the operation \uparrow^0 increases the priority of no state on this loop, and thus P remains a 0-loop in the automaton $\mathcal{A} \uparrow^0$. Therefore, q is a 0-0-flower.

Now, let $i > 0$ and suppose the result holds for $i - 1$. Let $\Omega_{\leq i}(q) = m$. Again, if $m > i$, the claim is trivial, so we can assume $m \leq i$.

Let $G'_{\leq i}$ be the graph of \mathcal{A} restricted to the states where priority is not greater than i in the automaton $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^{i-1}$. Let $m' = \Omega_{\leq i-1}(q)$. By the induction hypothesis, q is an $m'-(i-1)$ -flower in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^{i-1}$.

We consider two cases (clearly $m' \leq m$):

1. Suppose $m' = m$, i.e., the operation \uparrow^i has not changed the priority of q . This is possible only if there existed in $G'_{\leq i}$ an i -loop containing q . Call this loop P . Clearly, the operation \uparrow^i has not shifted the priority of any other node in the maximal strongly connected component of $G'_{\leq i}$ containing q . In particular, P continues to be an i -loop in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^i$. Furthermore every j -loop in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^{i-1}$ containing q , for $j < i$, remains a j -loop in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^i$. Since q is an $m'-(i-1)$ -flower in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^{i-1}$, it is an $m-i$ -flower in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^i$.
2. $m' < m$. The only possibility is $m = m' + 2$. By the definition of lifting (Definition 10), this means that the operation \uparrow^i has shifted by 2 the priorities of all the states in the maximal strongly connected component of $G'_{\leq i}$ containing q . Thus, every loop containing q that was a j -loop in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^{i-1}$, with $j < i$, has become a $(j+2)$ -loop in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^i$. Since q is an $m'-(i-1)$ -flower in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^{i-1}$, it is an $m-(i+1)$ -flower in $\mathcal{A} \uparrow^{0\uparrow^1} \dots \uparrow^i$. Hence *a fortiori* an $m-i$ -flower.

□

Definition 13. We say that a language $L \subseteq \Sigma^\omega$ **admits an m - n -flower** if there exists a deterministic Mostowski automaton \mathcal{A} , such that $L = L(\mathcal{A})$ and \mathcal{A} has an m - n -flower q for some q not useless state in \mathcal{A} (i.e., q occurring in some accepting run of \mathcal{A}).

Lemma 14 (Flower Lemma). *For every $n \in \mathbb{N}$ and $L \subseteq \Sigma^\omega$: (1) if L is 1- $(n+1)$ -unfeasible then L admits a $2i-(2i+n)$ -flower, for some i ; (2) if L is 0- n -unfeasible then L admits a $(2i+1)-(2i+1+n)$ -flower, for some i .*

Proof. We prove (1) and leave (2) to the reader.

Let $L = L(\mathcal{A})$ for some deterministic Mostowski automaton \mathcal{A} . We can assume without a loss of generality that \mathcal{A} has no useless states. Clearly, for arbitrary k , the operation \uparrow^k preserves this property.

Let M be the maximal value of the priority function of \mathcal{A} . Choose i such that $2i + n > M$. Consider the automaton $\mathcal{B} = \mathcal{A} \uparrow^{0 \uparrow^1} \dots \uparrow^{2i+n}$. By Lemma 11, $L(\mathcal{B}) = L$. If we can find a state q whose priority in \mathcal{B} is less or equal to $2i$ then we are done since, by Lemma 12, q is a $2i$ -($2i+n$)-flower in \mathcal{B} , and by the remark above q is not useless.

Suppose on the contrary that the minimal value of the priorities of all states in \mathcal{B} is $j > 2i$. It should be clear that the maximal priority of a state in \mathcal{B} cannot exceed $2i + n + 1$. (The operation \uparrow^k can change the priority of a state to at most $k + 1$.) By adding, if necessary, some dummy states we obtain that L is $(2i + 1)$ -($2i + 1 + n$)-feasible. By scaling the priorities down we conclude that L is 1 -($n + 1$)-feasible, contradicting the assumption. \square

For a given automaton \mathcal{A} and a given integer i one can calculate $\mathcal{A} \uparrow^i$ in the time proportional to the number of transitions in \mathcal{A} . Hence one can compute $\mathcal{A} \uparrow^1 \dots \uparrow^n$ in time $\mathcal{O}(n|\mathcal{A}|)$; where $|\mathcal{A}|$ denotes the number of transitions in \mathcal{A} . As we can easily limit the range of the Ω function to be at most twice as big as the number of states in \mathcal{A} we get:

Corollary 15. *The problem of establishing the index of the language accepted by an automaton with a Mostowski condition can be solved in time $\mathcal{O}(|\mathcal{A}|^2)$.
Deterministic*

4 The main result

Proposition 16. 1. *If a language $L \subseteq \Sigma^\omega$ admits a $2m$ -($2m + n$)-flower for some m , then $\text{Path}(L)$ is 1 -($n + 1$)-unfeasible.*
2. *If a language $L \subseteq \Sigma^\omega$ admits a $(2m + 1)$ -($2m + 1 + n$)-flower for some m , then $\text{Path}(L)$ is 0 - n -unfeasible.*

Proof. We shall prove 1, the case of 2 is analogous.

Let \mathcal{A} be a deterministic Mostowski automaton recognizing L and let q be a $2m$ -($2m + n$)-flower in \mathcal{A} , where q is not useless.

Suppose on the contrary that $\text{Path}(L)$ is 1 -($n + 1$)-feasible, and let:

$$\mathcal{C} = \langle \Sigma, Q^c, q_0^c, \text{Tr}^c, \Omega^c : Q^c \rightarrow \{1, \dots, n + 1\} \rangle$$

be a nondeterministic Mostowski automaton of index $(1, n + 1)$ recognizing $\text{Path}(L)$. Without a loss of generality we may assume that there are no useless states in \mathcal{C} .

From \mathcal{C} we shall construct a tree automaton \mathcal{D} of the same index, but over the alphabet $\{0, \dots, n\}$, that will recognize $\text{Path}(M_n)$. This, however, will contradict Theorem 7 and will prove that an automaton \mathcal{C} cannot exist.

To this end, we shall use our flower q in \mathcal{A} . For every $i = 0, \dots, n$ fix a word w_i , such that, there is a $(2m + i)$ -loop from q to q in \mathcal{A} labelled by w_i . Clearly, this is possible by the definition of a flower.

Apart from w_0, \dots, w_n , fix also a finite word v that is a labeling of a path in \mathcal{A} from the initial state to q . For notational convenience we assume that the

length of v as well as all w_i ($i = 1, \dots, n$) is k . The general case, when the lengths of v and w_i are different, requires more complex indexing.

Before defining formally an automaton for $\text{Path}(M_n)$, we explain its idea. It is based on a transformation of trees over the alphabet $\{0, \dots, n\}$ into trees over the alphabet Σ . This transformation essentially replaces a node labelled by $i \in \{0, \dots, n\}$ by a finite path labelled by w_i . Then, when examining a tree t (over the alphabet $\{0, \dots, n\}$), our automaton \mathcal{D} will mimic the work of the automaton \mathcal{C} on the transformed tree. This will be done in such a way that a computation of \mathcal{D} along a path labelled by $i_0 i_1 i_2 \dots$ ($i_\ell \in \{0, \dots, n\}$) will essentially simulate a computation of \mathcal{C} along a path labelled $vw_{i_0} w_{i_1} w_{i_2} \dots$.

Let a function $h : \{1, 2\}^* \rightarrow \{1, 2\}^*$ be defined by:

$$h(d_1 \dots d_i) = 1^{k-1} d_1 1^{k-1} \dots d_i 1^{k-1}$$

Let us denote by R the smallest tree containing the range of h .

We define an operation transforming a labelled tree $\tau : \{1, 2\}^* \rightarrow \{0, \dots, n\}$ into a labelled tree $\tau^\# : R \rightarrow \Sigma$. For arbitrary $u \in \{1, 2\}^*$, $d \in \{1, 2\}$ and $i \in \{0, \dots, k-1\}$ we let:

$$\begin{aligned} \tau^\#(1^i) &= \text{the } (i+1)\text{th letter of } v \\ \tau^\#(h(u)d1^i) &= \text{the } (i+1)\text{th letter of } w_{\tau(u)} \end{aligned}$$

The key property of this transformation is the following:

$$\begin{aligned} &\text{for every path } P = d_1 d_2 \dots \text{ in } \text{dom}(\tau) \text{ } (d_\ell \in \{1, 2\}), \text{ there is a path } P^\# = \\ &1^{k-1} d_1 1^{k-1} d_2 1^{k-1} \dots \text{ in } \text{dom}(\tau^\#) \text{ and this path is labelled by } \tau^\#(P^\#) = \\ &vw_{\tau(\varepsilon)} w_{\tau(d_1)} w_{\tau(d_1 d_2)} \dots \end{aligned}$$

Now, it follows from the choice of the words v, w_0, \dots, w_n , that an infinite word of the form $vw_{i_1} w_{i_2} \dots$ is in $L = L(\mathcal{A})$ iff $\limsup_{\ell \rightarrow \infty} i_\ell$ is even. In particular, we note the following.

Observation 17. For every infinite path P in the tree τ we have: $\tau^\#(P^\#) \in L$ iff $\tau(P) \in M_n$.

Now, we define the automaton:

$$\mathcal{D} = \langle \Sigma^d, Q^d = Q^c \times \{1, \dots, n+1\} \cup \{q_s\}, q_s, Tr^d, \Omega^d : Q^d \rightarrow \{1, \dots, n+1\} \rangle$$

where $\Sigma^d = \{0, \dots, n\}$ and the meanings of the other components are defined below.

The state q_s is the initial state and it will be used only in the starting move of \mathcal{D} . For the function Ω^d , we let $\Omega^d(q, i) = i$. We let $\Omega^d(q_s) = 1$ but this value does not really matter.

Before defining the transition function let us introduce an auxiliary notion. We say that a pair of states $q_l, q_r \in Q^c$ is *i-reachable* from a state $q_1 \in Q^c$ on a word $w = a_1 \dots a_k \in \Sigma^*$ if there is a sequence of transitions from Tr^c :

$$\langle q_1, a_1, q_2, q'_2 \rangle, \langle q_2, a_2, q_3, q'_3 \rangle, \dots, \langle q_{k-1}, a_{k-1}, q_k, q'_k \rangle, \langle q_k, a_k, q_l, q_r \rangle$$

and $i = \max(\Omega(q_1), \dots, \Omega(q_k))$.

Now, for every $a \in \{1, \dots, n\}$, we let $\langle q_s, a, (q_l, i), (q_r, i) \rangle \in Tr^d$ if (q_l, q_r) is i -reachable from the initial state q_0^c of \mathcal{C} on the word v . Also, we put a tuple $\langle (q, i), m, (q_l, j), (q_r, j) \rangle \in Tr^d$ if (q_l, q_r) is j -reachable from q on the word w_m .

To prove the claim it is enough to show that $L(\mathcal{D}) = \text{Path}(M_n)$. With the help of the operation \sharp introduced above, we can state the correspondence between \mathcal{C} and \mathcal{D} .

Observation 18. For every tree $\tau : \{1, 2\}^* \rightarrow \{0, \dots, n\}$ we have: $\tau \in L(\mathcal{D})$ iff τ^\sharp can be extended to a full binary tree that is accepted by \mathcal{C} .

Recall that \mathcal{C} accepts a tree iff the labeling of every path of this tree is accepted by \mathcal{A} . So, if \mathcal{C} accepts an extension of τ^\sharp then in particular $\tau^\sharp(P^\sharp) \in L(\mathcal{A}) = L$, for each path P in $\text{dom}(\tau)$. By Observation 17, we conclude that $\tau \in \text{Path}(M_n)$. We have proved $L(\mathcal{D}) \subseteq \text{Path}(M_n)$.

For the converse inclusion, let $\tau \in \text{Path}(M_n)$. Then clearly τ^\sharp can be extended to a tree in $\text{Path}(L)$. The conclusion now follows from the hypothesis that $L(\mathcal{C}) = \text{Path}(L)$. \square

Theorem 19. For every $L \subseteq \Sigma^\omega$ and $m, n \in \mathbb{N}$: L is m - n -feasible if and only if $\text{Path}(L)$ is m - n -feasible.

Proof. The implication “only if” follows from Proposition 8.

Suppose L is m - n -unfeasible. The case of $m > n$ is trivial, so we can assume $m \leq n$.

Suppose m is even. Then clearly L is also 0 -($n-m$)-unfeasible since otherwise we could scale up the priorities in the hypothetical automaton by m . By the Flower Lemma, L admits a $(2i+1)$ -($2i+1+n-m$)-flower, for some i , and then by Proposition 16, $\text{Path}(L)$ is 0 -($n-m$)-unfeasible. Hence clearly it is also m - n -unfeasible, since otherwise we could scale down the hypothetical automaton by m .

If m is odd, we present it as $m = m' + 1$, and the rest of the argument is similar. \square

From the connections between indices of Mostowski and Rabin automata (cf. [11]) we obtain:

Corollary 20. For every $L \subseteq \Sigma^\omega$ and $n \in \mathbb{N}$, L can be recognized by a deterministic Rabin automaton of index n if and only if $\text{Path}(L)$ can be recognized by a nondeterministic Rabin tree automaton of index n .

Finally let us remark on the problem of constructing a deterministic automaton recognising L from a nondeterministic tree automaton recognizing $\text{Path}(L)$. This can be done by constructing a nondeterministic automaton recognizing L , determinizing it and then applying our index lifting procedure from the flower lemma. The so-obtained deterministic automaton would have the least possible index.
