# **Generating Plans from Proofs**

MICHAEL BENEDIKT, University of Oxford BALDER TEN CATE, LogicBlox and UC-Santa Cruz EFTHYMIA TSAMOURA, University of Oxford

We present algorithms for answering queries making use of information about source integrity constraints, access restrictions, and access costs. Our method can exploit the integrity constraints to find plans even when there is no direct access to relations appearing in the query. We look at different kinds of plans, depending on the kind of relational operators that are permitted within their commands. To each type of plan, we associate a semantic property that is necessary for having a plan of that type. The key idea of our method is to move from a search for a plan to a search for a proof of the corresponding semantic property, and then *generate a plan from a proof*. We provide algorithms for converting proofs to plans and show that they will find a plan of the desired type whenever such a plan exists. We show that while discovery of one proof allows us to find a single plan that answers the query, we can explore alternative proofs to find lower-cost plans.

### 1. INTRODUCTION

This work concerns translating a *declarative source query* written in one vocabulary into a *target plan* that abides by certain *interface restrictions*. By a declarative source query, we will always mean a fragment of first-order logic, or its equivalent in SQL. We will focus on queries given in the language of *conjunctive queries*, equivalent to SQL basic SELECT queries. By a plan, we may mean a program that constructs query answers by interfacing with stored data.

What do we mean by an interface restriction on the target plan? The most basic kind of restriction is a *vocabulary-based restriction*, where the restriction is on the set of relations that are allowed to be referenced in the plan. We begin with a query Q written over relations  $R_1 \ldots R_j$ , and want to convert it to query Q' making use of a different set of relations  $V_1 \ldots V_k$ . Of course, if conjunctive queries Q and Q' mention different relations, Q cannot be equivalent to Q' on arbitrary instances. But our schema will

22:2 M. Benedikt et al.

come with *integrity constraints* that restrict the possible instances of interest. We will thus be considering equivalence only on instances satisfying the constraints.

The most basic example of vocabulary-based restriction comes from reformulating queries over views. We have a collection of view relations  $V_1 \dots V_k$ , where each  $V_i$  is associated with a query  $Q_i$  over some other set of relations  $R_1 \dots R_j$ . Given a query Q over  $R_1 \dots R_j$ , the goal is to find a query Q that mentions only  $V_1 \dots V_k$  where Q is equivalent to Q over all instances I for  $R_1 \dots R_j$ , where the instances are extended to  $V_1 \dots V_k$  by interpreting each  $V_i$  by  $Q_i(I)$ . Such a Q is called a reformulation of Q over the views. Generally, additional restrictions will be put on Q—for example, it should be a conjunctive query, or a union of conjunctive queries, or definable in relational calculus. The view-based query reformulation problem can thus be seen as a special case of vocabulary-based restriction, where the integrity constraints are of the form

$$\forall x_1 \dots \forall x_n \ V_i(x_1 \dots x_n) \leftrightarrow Q_i(x_1 \dots x_n).$$

The information available via an interface may or may not be sufficient to answer a query. The reformulation problem in this case is to determine whether there is sufficient information, and if so to generate a query making use of the view predicates.

*Example* 1.1. Consider a database with a table Professor containing ids, last names, and departments of professors, as well as a table Student listing the id and last name of students, as well as their advisor's id.

The database does not allow users to access the Professor and Student table directly, but instead exposes a view Professor' where the id attribute is dropped, and a table Student' where the advisor's id is replaced with the advisor's last name.

That is, Professor' is a view defined by the query

{Iname, dname | ∃profid Professor(profid, Iname, dname)}

or equivalently by the constraints

∀profid ∀lname ∀dname Professor(profid, lname, dname) → Professor'(lname, dname)

∀Iname ∀dname Professor'(Iname, dname) → ∃profid Professor(profid, Iname, dname).

Student' is a view defined by the query

{studid, Iname, profname |

 $\exists profid \ \exists dname \ Student(studid, Iname, profid) \land Professor(profid, profname, dname) \}$  or equivalently by constraints

∀studid ∀Iname ∀dname ∀profid ∀profname

Professor(profid, profname, dname) ∧ Student(studid, Iname, profid) →

Student'(studid, Iname, profname)

∀studid ∀lname ∀profname [Student'(studid, lname, profname) →

∃profid ∃dname Professor(profid, profname, dname) ∧ Student(studid, lname, profid)].

Consider a query asking for the last names of all students that have an advisor in the history department. This query *cannot* be answered using the information in the views, since knowing the advisor's name is not enough to identify the department.

On the other hand, the views are clearly sufficient to answer a query asking for the last names of students whose advisor has the last name Jones, and we can reformulate that query as a selection over Student' on profname "Jones."

Naturally, constraints need not come from views. A natural use of constraints is to represent *relationships between sources*, such as overlap in the data. This overlap can

be exploited to take a query that is specified over a source that a priori does not have sufficient data and reformulate it over a source that provides the necessary data.

Example 1.2. We consider an example schema from Onet [2013] with a relation Employee where a row contains an employee's id, the employee's name, and the id of the employee's department, and also a relation Department, with each row containing the department's id, the department's name, and the id of the department's manager.

The schema also contains the following two constraints:

 $\forall$ deptid  $\forall$ dname  $\forall$ mgrid Department(deptid, dname, mgrid)  $\rightarrow \exists N$  Employee(mgrid, N, deptid)  $\forall$ eid  $\forall$ ename  $\forall$ deptid Employee(eid, ename, deptid)  $\rightarrow \exists D \exists M$  Department(deptid, D, M).

That is, every department has a manager, and every employee works in a department. Suppose further that only the relation Department is accessible to a certain class of users. Intuitively, it should still be possible to answer some questions that one could ask concerning the relation Employee, making use of the accessible relation Department.

For example, suppose a user poses the query asking for all department ids of employees, writing it like this:

 $Q = \{ deptid \mid \exists eid \exists ename Employee(eid, ename, deptid) \}.$ 

Renaming the variables, the query can be reformulated as

 $Q' = \{ deptid \mid \exists dname \exists mgrid Department(deptid, dname, mgrid) \}.$ 

Access methods and binding patterns. We will look at a finer notion of interface based on binding patterns, which state that a relation can only be accessed via lookups where certain arguments must be given. The most obvious example is a relation that can only be accessed via an indexed lookup on a certain subset of the attributes. Another example of restricted interfaces that can be modeled using relations with binding patterns comes from web forms. Thinking of the form as exposing a virtual table, the mandatory fields must be filled in by the user, while submitting the form returns all tuples that match the entered values. A third example comes from web services, where the mandatory fields correspond to arguments of a function call.

Example 1.3. Consider a Profinfo table containing information about faculty, including their last names, office number, and id, but with a restricted interface that requires giving an id as an input. The query Q asking for ids of faculty named "Smith" cannot be answered over this schema. That is, there is no query over the schema that will return exactly the set of tuples satisfying Q.

But suppose another source has a Udirectory table containing the id and last name of every university employee, with an interface that allows one to access the entire contents of the table. Then we can reason that Q has a plan that answers it: a plan would pull tuples from the Udirectory table, select those corresponding to "Smith," and check them within the Profinfo table.

In the previous example, reasoning about access considerations was straightforward, but in the presence of more complex schemas we may have to chain several inferences, resulting in a plan that may make use of several auxiliary accesses.

Example 1.4. We consider two telephone directory data sources with overlapping information. One source exposes information from Direct1(uname, addr, uid) via an access requiring a uname and uid. There is also a table lds(uid) with no access restriction that makes available the set of uids (hence a referential constraint from Direct1 into lds on uid). The other source exposes Direct2(uname, addr, phone), requiring a uname and addr, and also a table Names(uname) with no access restriction that reveals all 22:4 M. Benedikt et al.

unames in Direct2 (i.e., a referential constraint from Direct2 to Names). There is also a referential constraint from Direct2 to Direct1 on uname and addr. Consider a query asking for all phone numbers in the second directory:

 $Q = \{ phone \mid \exists uname \exists addr Direct2(uname, addr, phone) \}.$ 

There is a plan that answers this query: it gets all the uids from Ids and unames from Names first, puts them into the access on Direct1, then uses the uname and addr of the resulting tuples to get the phone numbers in Direct2.

We emphasize that our goal in this work is getting plans that give *complete answers* to queries. This means that if we have a query asking for the office number of all professors with the last name "Smith," the plan produced should return all tuples in the answer, even if access to the Professor relation is limited.

We will look at getting not just any plan in the target language, but one with low cost. Examples of access cost include the cost in money of accessing certain services and the cost in time of accessing data through either making web service calls, iteratively inputting into web forms, or using particular indices.

**Plan generation approach.** The article will overview a general approach that emerged from mathematical logic (starting with the work of William Craig [Craig 1957]) adapted to the database setting by Segoufin and Vianu [2005]. The "meta-algorithm" for plan generation is as follows:

- (1) Isolate a *semantic property* that any input query Q must have with respect to the class of target plans and constraints  $\Sigma$  in order to have an equivalent plan of the desired type.
- (2) Express this property as a *proof goal* (in the language we use later on, an *entailment*): a statement that formula  $\varphi_2$  follows from  $\varphi_1$ .
- (3) Search for a proof of the entailment, within a given proof system. Here we will focus on chase proofs, a well-known proof system within databases.
- (4) From the proof, extract a plan.

We will show that this approach can be applied to a variety of restrictions on the plan, with different plan targets corresponding to different entailments. We prove a number of theorems saying that the method is complete: there is a plan exactly when there is a proof of the property. These completeness theorems give as a consequence a *definability or preservation theorem*: a query Q has a certain kind of plan if and only if it has a certain semantic property.

Thus, our results will link a semantic property of Q (with respect to  $\mathcal{T}$  and  $\Sigma$ ), the existence of a certain kind of plan equivalent to Q, and a proof goal such that from a proof we can generate the desired plan.

Adding on cost considerations. In the setting of overlapping data sources, there can be many plans with very distinct costs. Consider a variant of Example 1.3 in which there are two tables Udirectory<sub>1</sub> and Udirectory<sub>2</sub> that contain the necessary information. In this case, we would have at least three plans: one that first accesses Udirectory<sub>1</sub> as above and then checks the results in Profinfo, another that first accesses Udirectory<sub>2</sub>, and a third that accesses both Udirectory<sub>1</sub> and Udirectory<sub>2</sub> and intersects the results in middleware before doing the check in Profinfo. Which of these is best will depend on how costly access is to each of the directory tables, and what percentage of the tuples in the two directory tables match a result in Profinfo. Notice that these plans are not variants of one another, and one cannot be obtained from the other by applying algebraic transformations. We will present an algorithm that will find the lowest-cost plan for a class of cost functions on access plans. The main idea is to explore the full space of proofs, but guiding the search by cost as well as proof structure. Thus, instead of generating a single proof and then sending the corresponding plan on for further

optimization, we interleave exploration of proofs with calls to estimate cost of (and perhaps further optimize) the corresponding plans.

**Organization.** We start by giving preliminaries on database schemas, query languages, and logics (Section 2), along with the plan language and associated query answering problems that we study in this work. Section 3 justifies the choice of plan language by showing its equivalence to other formalisms for defining queries that conform to access methods. Section 4 provides the proof goals that correspond to each kind of plan that we will be interested in, along with the corresponding semantic property. It then will present the main theorems of the article, stating the equivalence of a semantic property, existence of a plan, and existence of a certain kind of proof.

The basic plan generation algorithms that prove these theorems are presented in Section 5, which also shows that these algorithms always generate a correct plan from a proof. Coupled with earlier results from Section 4, this gives the main results on equivalence of proofs and plans in the article.

In Section 6, we turn to getting plans with low cost. Section 7 gives conclusions, while Section 8 gives an overview of related work.

#### 2. DEFINITIONS

**Logical notation.** We will use standard terminology for describing queries in first-order logic, including the notion of free variable, quantifiers, connectives, and so forth [Abiteboul et al. 1995].

If  $\varphi$  is a formula whose free variables include  $\vec{x}$  and  $\vec{t}$  is a sequence of constants and variables whose length matches  $\vec{x}$ , then  $\varphi(\vec{x} := \vec{t})$  denotes the formula obtained by substituting each  $x_i$  with  $t_i$ . We will often omit universal quantifiers from formulas, particularly for formulas where the only quantifiers are universal. For example, we will write  $P(x, y) \to Q(x, y)$  as a shorthand for  $\forall x \forall y [P(x, y) \to Q(x, y)]$ .

A relational schema contains a finite collection of schema constants and a finite collection of relations (or tables), each with an associated arity. We assume that distinct schema constants are associated with distinct value and will identify the constant and the value. A database instance (or just instance) I for schema Sch assigns to every relation R in Sch a collection of tuples I(R) of the right arity, in such a way that any integrity constraints of Sch are satisfied. We call I(R) the interpretation of R in I. An association of a database relation R with a tuple  $\vec{c}$  of the proper arity will be referred to as a fact. A database instance can equivalently be seen as a collection of facts. The  $active\ domain$  of an instance I is the union of the one-dimensional projections of all interpretations of relations: that is, all the elements that participate in some fact of I. When evaluating first-order formulas, we always assume the  $active\ domain\ semantics$  in which quantifiers range over the active domain of the instance.

In our plan generation problems, we have some "visible" information (e.g., a set of relations that our programs are allowed to access) and have to consider what underlying instance is consistent with that. The notion of superinstance captures that an instance I' is consistent with the information provided by another instance I. If we have two instances I and I', and for every relation R,  $I(R) \subseteq I'(R)$ , then we say that I is a subinstance of I', and I' is a superinstance of I.

**Queries.** By a query we mean a mapping from relation instances of some schema to instances of some other relation. A Boolean query is a query where the output is a relation of arity 0. Since there are only two instances for a relation of arity 0, a Boolean query is a mapping where the output takes one of two values, denoted True and False. Given a query Q and instance I, Q(I) is the result of evaluating Q on I.

First-order logic sentences clearly can be used to define Boolean queries: given an instance, the result of the query is True exactly when the sentence holds in the instance. Given a first-order logic formula with its free variables enumerated as  $v_1 ldots v_n$ , we can

22:6 M. Benedikt et al.

associate a non-Boolean query whose output relation has arity n, whose output on an instance I is the set of n-tuples of values  $\vec{t}$  in the active domain of I for which the instance and the corresponding binding  $v_1 := t_1 \dots v_n := t_n$  satisfies the formula. For an instance I, formula  $\varphi$ , and a binding bind for the variables of  $\varphi$ , we will write I, bind  $\models \varphi$  to mean that bind satisfies  $\varphi$  in I.

**Relational algebra.** An alternative notation for relations is to consider them as having named attributes. Relational algebra is a query language that references relations by name, using operations selection, projection, renaming, difference, and join, along with an operator for each schema constant (taking no input and producing a single-attribute table whose sole cell contains that constant). The USPJ fragment disallows the use of difference, while the USPJ fragment allows the difference operator E-E' to be applied only when  $E'=E\bowtie_{\sigma}R$ , where R is a relation symbol and  $\sigma$  is a set of equality conditions identifying each attribute of R with an attribute of E. In the USPJ fragment, we allow for the use of inequalities in selections and join conditions. The SPJ fragment further restricts USPJ by not allowing union.

All of our fragments will, by convention, include the empty expression, denoted  $\emptyset$ , which always returns the empty set of tuples. We will freely move back and forth between logic-based notation and relational algebra notation, and also between positional and attribute-based notation for components of a tuple.

Relational algebra Boolean queries are those that have no attributes as output. It is well known that every relational algebra Boolean query can be efficiently converted into an active-domain first-order logic formula and vice versa [Abiteboul et al. 1995].

**Queries and constraints of particular interest.** The problems we look at will generally have as inputs both a query and a set of constraints. For queries, we will look at *conjunctive queries*, logical formulas of the form  $Q(\vec{x}) = \exists \vec{y} (A_1 \land \cdots \land A_n)$ , where  $A_i$  is an atom using a relation of the schema, with arguments that are either variables from  $\vec{x}$  and  $\vec{y}$  or constants from the schema. Conjunctive queries are equivalent to queries defined in the SPJ fragment of relational algebra.

Existential formulas are those of the form  $\exists x_1 \dots x_n \varphi$ , where  $\varphi$  is built up using the Boolean operators. Existential formulas are equivalent in expressiveness to queries in the  $USPJ^-$  fragment of relational algebra.

Although some of our results apply to constraints given by arbitrary first-order logic sentences, we will focus our attention on constraints given by *tuple-generating dependencies* (TGDs), given syntactically as

$$\forall \vec{x} \ [\varphi(\vec{x}) \rightarrow \exists \vec{y} \ \rho(\vec{x}, \vec{y})],$$

where  $\varphi$  and  $\rho$  are conjunctions of relational atoms, possibly including constants.

A special subclass consists of Guarded TGDs (GTGDs), in which  $\varphi$  is of the form  $R(\vec{x}) \wedge \varphi'$ , where  $R(\vec{x})$  contains all variables of  $\varphi'$ . These in turn subsume *inclusion dependencies* (IDs): where  $\varphi$  and  $\rho$  are single atoms in which no variables are repeated and there are no constants. IDs are also called "referential constraints." An inclusion dependency with  $\varphi = \forall \vec{x} \ \forall \vec{u} \ R(\vec{x}, \vec{u}) \rightarrow \exists \vec{y} \ S(\vec{x}, \vec{y})$  can also be written in the form  $R[j_1 \dots j_n] \rightarrow S[k_1 \dots k_n]$ , where  $j_i$  is the position containing exported variable  $x_i$  in  $R(\vec{x}, \vec{y})$  and  $k_i$  is the corresponding position containing  $x_i$  in the atom  $S(\vec{x}, \vec{y})$ . For example, the ID  $\forall x \ \forall u \ R(x, u) \rightarrow \exists y \ S(y, x)$  would be written  $R[1] \rightarrow S[2]$ .

An access schema consists of:

- —A collection of relations, each of a given arity. A *position* of a relation R is a number  $\leq arity(R)$ .
- —A finite collection C of schema constants ("Smith", 3, ...). Informally, these represent a fixed set of values that a querier might use as test values in accesses. For example, if the user is performing a query involving the string "Smith," we would assume that

"Smith" was a schema constant—but not arbitrary unrelated strings. In particular, we will assume that all constants used in queries or constraints are schema constants.

- —For each relation R, a collection (possibly empty) of *access methods*. Each method mt is associated with a collection of positions of R—the *input positions* of mt.
- —Integrity constraints, which we will take to be always sentences in first-order logic.

An access (relative to a schema as earlier) consists of an access method of the schema and a binding—a function assigning values to every input position of the method. If mt is an access method on relation R with arity n, I is an instance for a schema that includes R, and AccBind is a binding for mt, then the output or result of the access (mt, AccBind) on I is the set of n-tuples  $\vec{t} \in I(R)$  such that  $\vec{t}$  restricted to the input positions of mt is equal to AccBind.

We will be looking for programs that interact with a data source by generating accesses and manipulating the output with queries. As in most database settings, we will look for programs that use a restricted set of operators.

An access command over a schema Sch with access methods is of the form

$$T \Leftarrow_{\mathsf{OutMap}} \mathsf{mt} \Leftarrow_{\mathsf{InMap}} E$$
,

where (1) E is a relational algebra expression E over some set of relations not in Sch ("temporary tables" henceforward); (2) mt is a method from Sch on some relation R; (3) InMap, the  $input\ mapping$  of the command, is a function from the output attributes of E onto the input positions of mt; (4) T, the  $output\ table$  of the command, is a temporary table; and (5) OutMap, the  $output\ mapping$  of the command, is a bijection from positions of R to attributes of T. Note that an access method may have an empty collection of input positions. In such a case, the corresponding access is defined over the empty binding, and an access command using the method must take the empty relation algebra expression  $\emptyset$  as input. In other words, the access method makes the relation freely accessible. In Example 1.3, the Udirectory table was assumed to have such an "input-free" access method.

A middleware query command is of the form T := Q, where Q is a relational algebra query over temporary tables and T is a temporary table. A return command is of the form Return E, where E is a relational algebra expression as earlier. An RA-plan consists of a sequence of access and middleware query commands, along with at most one return command.

When writing access commands, we will omit the mappings for readability when they are clear from context. Returning to Example 1.3, a plan that is equivalent to the query would be represented as follows, with mt<sub>Udirectory</sub> and mt<sub>Profinfo</sub> being the methods on the corresponding tables:

$$T_1 \Leftarrow \mathsf{mt}_{\mathsf{Udirectory}} \Leftarrow \emptyset$$
  $T_2 := \pi_1(\sigma_{\#2=\mathsf{``Smith''}}T_1)$   $T_3 \Leftarrow \mathsf{mt}_{\mathsf{Profinfo}} \Leftarrow T_2$   $\mathsf{Return}\,\pi_{\mathsf{eid}}T_3.$ 

A temporary table is *assigned* in a plan if it occurs on the left side of a command, and otherwise is said to be *free*. The semantics of plans is defined as a function that takes as input an instance I for Sch and interpretations of the free tables. If the plan has no Return statement, the output consists of interpretations for each assigned temporary table. If the plan contains a statement Return E, the output is an interpretation of a relation with attributes for each output attribute of E. In the latter case, we refer to this as the *output* of the plan. An access command  $T \leftarrow_{\mathsf{OutMap}} \mathsf{mt} \leftarrow_{\mathsf{InMap}} E$  is executed by evaluating the expression E on I and "accessing  $\mathsf{mt}$  on every result tuple." That is,

22:8 M. Benedikt et al.

each output tuple of E is mapped to a tuple  $t_{j_1} \dots t_{j_m}$  using the input mapping InMap. For each tuple  $\vec{t} = t_1 \dots t_n \in R$  that "matches" (i.e., that extends)  $t_{j_1} \dots t_{j_m}$ ,  $\vec{t}$  is transformed to a tuple  $\vec{t}'$  using the output mapping OutMap. The interpretation of T is then the union of all such tuples  $\vec{t}'$ . A middleware query command T := E executes query E on the contents of the temporary tables mentioned in E and assigns the result to temporary table T.

A plan is evaluated by evaluating each command in sequence, with each command operating on the instance formed from the input instance by adding the interpretations of assigned tables produced by earlier commands. For a plan having as its final command Return E, the output of the plan is the evaluation of E on the instance formed as earlier.

In RA-plans, we allowed arbitrary relational algebra expressions in both the inputs to access commands and the middleware query commands. We can similarly talk about SPJ-plans, where the expressions in access and middleware query commands are built up from relational algebra operators SELECT, PROJECT, and JOIN, along with renaming and constant operators for each schema constant. USPJ-plans allow UNION in addition to SPJ operators.

We define *USPJ*-*plans* as any RA-plans in which relational algebra's difference operator only occurs in a *nonmembership check*, which tests whether the tuples in a projection of a temporary table are not in a given relation *R*. Formally, a nonmembership check is a sequence of two commands:

$$T' \Leftarrow_{\mathsf{OutMap}} \mathsf{mt} \Leftarrow_{\mathsf{InMap}} \pi_{a_{j_1} \dots a_{j_m}}(T)$$
  $T'' \coloneqq T - (T \bowtie T').$ 

where in the first command, (1) mt is an access method on some relation R with input positions  $j_1 \dots j_m$ , (2) the input mapping InMap maps attribute  $a_{j_i}$  to position  $j_i$ , (3) the attributes of the output table T' are a subset of the attributes of T and contain every  $a_{j_i}$ , (4) and the output mapping OutMap maps position  $j_i$  back to  $a_{j_i}$ . In the second command, the join condition identifies attributes that have the same name.

**Plans that answer queries.** We now formalize the notion of a plan being "correct" for a query. Given an access schema Sch, a plan answers a query Q (over all instances) if for every instance I satisfying the constraints of Sch, the output of the plan on I is the same as the output of Q. We say that the plan answers Q over finite instances if this holds for every finite instance I satisfying the constraints. Throughout this article, we will be concerned with plans that answer a query over all instances, and we will just say the plan answers Q (without qualification) to denote this. However, we will show that for the constraints we focus on here, there is no difference between answering over finite instances and answering over all instances.

**Cost.** A plan cost function associates every plan with a nonnegative integer cost. The minimal cost problem for an access schema Sch and integrity constraints, query Q, and cost function Cost is the problem of finding a plan that conforms to Sch and that answers Q (with respect to constraints in Sch) while having minimal value of Cost.

The general algorithmic approach we describe can be applied with an arbitrary cost function, but our completeness results will always require strong assumptions on cost. Given a plan PL whose access commands, ordered by appearance, are Command<sub>1</sub>...Command<sub>j</sub>, its *method sequence* denoted Methods(PL) is the sequence of  $\mathsf{mt}_1 \dots \mathsf{mt}_j$ , where  $\mathsf{mt}_i$  is the method used in Command<sub>i</sub>. We say that PL *uses no more methods than* PL', denoted PL  $\leq_{\mathsf{Meth}}$  PL', if the method sequence of PL is a subsequence (not necessarily contiguous) of the method sequence of PL'. A cost function Cost is simple if PL  $\leq_{\mathsf{Meth}}$  PL' implies  $\mathsf{Cost}(\mathsf{PL}) \leq \mathsf{Cost}(\mathsf{PL}')$ . For example, a function that takes

a weighted sum of the methods used in access commands within a plan would be a simple cost function.

#### 2.1. TGDs and the Chase

This work will deal with reasoning about logical formulas. A basic reasoning problem is to determine whether a  $\varphi_1$  entails another sentence  $\varphi_2$ , meaning that in any instance where  $\varphi_2$  holds,  $\varphi_1$  holds. We can also talk about a formula  $\varphi_1(\vec{x})$  entailing another formula  $\varphi_2(\vec{x})$ : this means that in any instance and any binding of the variables  $\vec{x}$  to elements of the instance, if  $\varphi_1(\vec{x})$  holds, then  $\varphi_2(\vec{x})$  holds. We write  $\varphi_1 \models \varphi_2$  to indicate that  $\varphi_1$  entails  $\varphi_2$ .

We recall that *proof systems* for logics are formal systems for showing that an entailment holds in the logic. A proof system is *complete* if every entailment that is true has a proof. If we use  $\rho(\vec{x}) \vdash \varphi(\vec{x})$  to denote that one can prove  $\varphi(\vec{x})$  from  $\rho(\vec{x})$ , for a complete proof system we have  $\rho(\vec{x}) \models \varphi(\vec{x})$  if and only if  $\rho(\vec{x}) \vdash \varphi(\vec{x})$ .

We will be interested in special kinds of entailments, of the form

$$Q \wedge \Sigma \models Q'$$

where Q and Q' are conjunctive queries and  $\Sigma$  is a conjunction of TGDs.

This entailment problem is often called "query containment with constraints" in the database literature. We often say that Q is contained in Q w.r.t.  $\Sigma$ . A specialized method has been developed for these problems, called *the chase* [Maier et al. 1979; Fagin et al. 2005].

A proof in the chase consists of a sequence of database instances, beginning with the canonical database of query Q: the database whose elements are the constants of Q plus copies  $c_1$  of each variable  $x_1$  in Q and which has a fact  $R(c_1 \ldots c_n)$  for each atom  $R(x_1 \ldots x_n)$  of Q. These databases evolve by firing rules. Given a set of facts I and a TGD  $\delta = \forall x_1 \ldots x_j \ \varphi(\vec{x}) \rightarrow \exists y_1 \ldots y_k \ \rho(\vec{x}, \vec{y})$ , a trigger for  $\delta$  is a tuple  $\vec{e}$  such that  $\varphi(\vec{e})$  holds. An active trigger is one for which there is no  $\vec{f}$  such that  $\rho(\vec{e}, \vec{f})$  holds in I. A rule firing for a trigger adds facts to I that make  $\rho(\vec{e}, \vec{f})$  true, where  $f_1 \ldots f_k$  are new constants ("chase constants") distinct from those in the schema. Such a firing is also called a chase step. If the trigger was an active trigger, it is a restricted chase step.

A chase sequence following a set of dependencies  $\Sigma$  consists of a sequence of instances  $\operatorname{config}_i: 1 \leq i \leq n$ , where  $\operatorname{config}_{i+1}$  is obtained from  $\operatorname{config}_i$  by some rule firing of a dependency in  $\Sigma$ . Thus, each  $1 \leq i \leq n$  is associated to an instance  $\operatorname{config}_i$  (a chase configuration), to a rule firing, and to a set of generated facts—the ones produced by the last rule firing. If Q is a conjunctive query and config is a chase configuration having elements for each free variable of Q, then a homomorphism of Q into config mapping each free variable into the corresponding element is called a match for Q in config. A chase proof for the entailment  $Q \wedge \Sigma \models Q$  is a chase sequence beginning with the canonical database of Q, applying chase steps with  $\Sigma$ , ending in a configuration having a match.

We now have the following well-known result, saying that the chase is a complete proof system for CQ containment under constraints:

Theorem 2.1 [Maier et al. 1979; Fagin et al. 2005]. For any instance I, for conjunctive queries Q and Q' with the same free variables, and any TGD constraints  $\Sigma$ , Q is contained in Q' w.r.t.  $\Sigma$  if and only if there is a chase sequence following  $\Sigma$  beginning with the canonical database of Q, leading to a configuration that has a match for Q'.

22:10 M. Benedikt et al.

*Example 2.2.* We recall the schema from Example 1.2, containing information about employees and departments. The constraints  $\Sigma$  were the following two TGDs:

 $\forall \mathsf{deptid} \, \forall \mathsf{dname} \, \forall \mathit{mgrid} \, \mathsf{Department}(\mathsf{deptid}, \mathsf{dname}, \mathsf{mgrid}) \to \exists N \, \mathsf{Employee}(\mathsf{mgrid}, N, \mathsf{deptid}) \\ \forall \mathsf{eid} \, \forall \mathsf{ename} \, \forall \mathsf{deptid} \, \mathsf{Employee}(\mathsf{eid}, \mathsf{ename}, \mathsf{deptid}) \to \exists D \exists M \, \mathsf{Department}(\mathsf{deptid}, D, M).$ 

Consider the following two queries:

 $Q = \{ deptid \mid \exists eid \exists ename Employee(eid, ename, deptid) \}$  $Q^* = \{ deptid \mid \exists eid \exists ename Department(eid, ename, deptid) \}.$ 

We claim that Q is contained in  $Q^*$  relative to the constraints of the schema, and in the more general logical terminology, that

$$Q \wedge \Sigma \models Q^*$$
.

To do this, we perform a chase proof.

We begin our proof with the "canonical database" of our assumption query  $Q = \exists \text{eid} \exists \text{ename Employee}(\text{eid}, \text{ename}, \text{deptid})$ . That is, we fix constants  $\text{eid}_0$ ,  $\text{ename}_0$ ,  $\text{deptid}_0$  witnessing the variables to get the "initial database":

 $Employee(eid_0, ename_0, deptid_0).$ 

We can now perform a "chase step" with the second integrity constraint, to derive a new fact:

Department(deptid<sub>0</sub>, D, M),

where D, M are new constants.

We can now match  $Q^*$  against the set of facts we have produced, with the homomorphism mapping the free variable deptid in  $Q^*$  to the corresponding constant deptid<sub>0</sub>. This chase proof witnesses that Q is contained in  $Q^*$  w.r.t.  $\Sigma$ .

One way to find a chase proof is to "chase an initial instance as much as possible." For any set of TGDs  $\Sigma$  and initial instance I, we could just fire rules in an arbitrary order, making sure that any rule that is triggered fires eventually. The union of all facts generated will give an instance that satisfies the constraints, but it may be infinite. We refer to this as the result of chasing I with  $\Sigma$ . There will be many such instances depending on the order of rules fired, but they will all satisfy the same conjunctive queries by Theorem 2.1.

Sometimes one can fully chase an initial instance and get a finite chase sequence and finite final configuration. A restricted chase sequence is one that makes only restricted chase steps (i.e., steps using active triggers). A finite restricted chase sequence terminates if in the final configuration there are no active triggers. That is, eventually no rules can fire that add new witnesses. If we have a terminating chase sequence beginning with the canonical database of Q, Theorem 2.1 implies that for any conjunctive query Q', Q is contained in Q' w.r.t. the constraints if and only if Q' has a match in the final configuration. If the constraints have the property that every long enough restricted chase sequence terminates, we will say that the constraints have terminating chase.

### 3. EXPRESSIVENESS OF PLAN LANGUAGES

The language of RA-plans described in the previous section allows one to express "first-order plans"—plans that perform accesses and manipulate the results in relational algebra, which is known to have the expressiveness of first-order logic. We will review two other formalisms for defining plans using RA or first-order logic and show that they give the same expressiveness as RA-plans. We will make use of this equivalence later in the article.

**Nested plans.** It will sometimes be convenient to program plans with a higher-level syntax that allows a notion of subroutine. We formalize this by defining an extension of RA-plans with subroutines, the *nested RA-plans*. We inductively define the syntax of nested plans, along with the definition of a temporary table being *free* or *assigned* within a nested plan, extending the definition for RA-plans in Section 2. While for RA-plans, every temporary table mentioned in the plan will be either free or assigned, this will not be the case for nested plans.

An atomic nested plan is either (1) an access command  $T \Leftarrow_{\text{OutMap}} \text{ mt} \Leftarrow_{\text{InMap}} E$ ; (2) a middleware query command T := E, where E is an RA expression over temporary tables and  $T_{\bar{x}}$ ; or (3) a command Return T, where T is a temporary table. In each case, T is the only assigned temporary table of the plan, and the tables mentioned in E are free tables.

Nested plans are built up via concatenation and *subplan calls*.

If  $PL_1$  and  $PL_2$  are nested plans, then  $PL_2 \cdot PL_1$  (read as " $PL_2$  followed by  $PL_1$ ") is a nested plan. The free tables are the free tables of  $PL_2$  along with any free tables of  $PL_1$  that are not assigned tables of  $PL_2$ . The assigned tables of the concatenation are the assigned tables of  $PL_2$  unioned with the assigned tables of  $PL_1$ .

If  $PL_1$  is a nested plan that includes a Return command at "top level" (not nested inside a subplan call), T is a free table in  $PL_1$ , E is an RA expression over temporary tables disjoint from those of  $PL_1$  whose output matches the attributes of T, and T' is a new temporary table whose attributes are those of the output of  $PL_1$ , then

$$T' \Leftarrow \mathsf{PL}_1[T] \Leftarrow E$$

is a nested plan. The assigned tables of this plan are the assigned tables of  $\mathsf{PL}_1$  along with T', while the free tables are those of  $\mathsf{PL}_1$  minus  $\{T\}$  along with any tables mentioned in E. Informally, this plan evaluates E to get a set of tuples  $I_E$ , performs  $\mathsf{PL}_1$  in parallel with the table T corresponding to  $\{\vec{t}\}$  for each tuple  $\vec{t}$  in  $I_E$ , and sets T' to be the union of each tuple  $\vec{o}$  in the output of such a call.

Formally, we can define the result of an assigned temporary table T in a nested plan PL, along with the output of such a plan, when evaluated with respect to an instance I for the Sch relations and all free temporary tables of PL. The evaluation of an access command is as before, the evaluation of a middleware query command is standard, and the evaluation of  $PL_2 \cdot PL_1$  is via evaluating  $PL_1$  on the expansion of the input via the evaluation of tables in  $PL_2$ . The evaluation of  $T' \Leftarrow PL_1[T] \Leftarrow E$  is

$$\bigcup_{\vec{t} \in E(I)} \mathsf{PL}_1(I,\, T \,:=\, \{\vec{t}\}),$$

where  $I, T := \{\vec{t}\}\$  is the instance formed from I by interpreting T as  $\{\vec{t}\}$ .

**Executable queries.** We now introduce another approach to describing plans. In the prior literature on querying with access methods, the emphasis has been on identifying syntactic restrictions on queries that guarantee that they can be implemented via access defined in an access schema. We review these notions of executable query next.

The notion of executability was first defined for conjunctive queries. A conjunctive query Q with atoms  $A_1 \ldots A_n$  is executable relative to a schema with access patterns [Li and Chang 2000] if there is an annotation of each atom  $A_i = R_i(\vec{x_i})$  with an access method  $\mathsf{mt}_i$  on R such that for each variable x of Q, for the first  $A_i$  containing x, x occurs only in an output position of  $\mathsf{mt}_i$ . A UCQ  $\bigvee_i Q_i$ , where  $Q_i$  is a CQ, is said to be executable if each disjunct is executable.

Executable UCQs are closed under projection, since one can push the projection inside the disjunction, and the requirements on the binding patterns are still satisfied.

22:12 M. Benedikt et al.

Every executable UCQ is clearly "implementable with access commands that use the given methods." In fact, every executable conjunctive query Q can be converted naïvely to an SPJ-plan PlanOf(Q).

Proposition 3.1. Every executable CQ can be converted to an SPJ-plan, where the number of access commands of the plan is equal to the number of atoms in the query. Similarly, every executable UCQ can be converted to a USPJ-plan.

PROOF. We inductively translated conjunctions of atoms to plans, with the base case translating the empty conjunction to the empty plan. The inductive rule will remove the Return command in PlanOf( $A_1 \dots A_{i-1}$ ) and append on (1) the access command  $T'_i \Leftarrow \mathsf{mt}_i \Leftarrow E_i(T_{i-1})$ , where  $\mathsf{mt}_i$  is the method annotating  $A_i$ , and  $E_i$  consists of SPJ operations that project onto the input positions of  $\mathsf{mt}_i$  and enforce repetition of variables and schema constants in input positions of  $\mathsf{mt}_i$ ; (2) the middleware command  $T_i := E'_i(T'_i) \bowtie T_{i-1}$ , where  $T_{i-1}$  is the output table of  $\mathsf{PlanOf}(A_1 \dots A_{i-1})$ , which will have attributes for all variables of  $A_1 \dots A_i$ , and  $E'_i$  consists of selections that enforce repetition of variables and schema constants in output positions of  $\mathsf{mt}_i$ ; and (3) the command Return  $T_i$ . A final projection operation will enforce any projections in Q. By translating one disjunct at a time, we see that every executable UCQ translates into a USPJ-plan.  $\square$ 

We wish to extend the notion of executability to first-order queries. Although a prior definition exists in the literature [Nash and Ludäscher 2004a], we will find it useful to build our own.

An FO formula is *executable for membership checks* (relative to an access schema Sch) if it is built up from equalities and the formula True using arbitrary Boolean operations and the quantifiers

$$\forall \vec{y} [R(\vec{x}, \vec{y}) \to \varphi(\vec{x}, \vec{y}, \vec{z})]$$
  
$$\exists \vec{y} R(\vec{x}, \vec{y}) \land \varphi(\vec{x}, \vec{y}, \vec{z}),$$

and for any such quantification, if R is an Sch relation, then R has an access method mt such that all of the input positions of mt are occupied by some  $x_i$  (i.e., by a variable or constant).

Notice that the definition of executable UCQ enforces restrictions related to the access methods on both quantification and the free variables. However, for formulas executable for membership checks, we enforce restrictions on quantification but impose no restriction on the free variables. Thus, we cannot be sure that such formulas can be implemented using the access methods. However, if we are given a tuple, we can check whether it satisfies the formula using the access methods.

Let  $\varphi(\vec{x})$  be a first-order formula using the schema relations and additional tables  $\vec{T}$ . Let PL be an RA-plan that has output attributes for each variable in  $\vec{x}$  and has free temporary tables contained in  $\vec{T} \cup \{T_{\vec{x}}\}$ , where  $T_{\vec{x}}$  is an additional temporary table with attributes for each variable in  $\vec{x}$ . We say that such a plan PL filters  $\varphi$  if

$$\mathsf{PL}(I^*) = \{ \vec{o}^* \mid \vec{o} \in I(T_{\vec{x}}) \land I, \vec{o} \models \varphi \},$$

where for a variable binding  $\vec{o}$  with free variables  $x_1 \dots x_n$ ,  $\vec{o}^*$  is the corresponding tuple with attributes  $a_1 \dots a_n$ , and  $I^*$  is the same as I except that free tables T with arity k are considered as tuples with attributes  $\#1 \dots \#k$ .

PROPOSITION 3.2. There is a linear time procedure taking as input a first-order formula  $\varphi$  with free variables  $x_{a_1} \dots x_{a_n}$  that is executable for membership checks and producing an RA-plan with output attributes  $a_1 \dots a_n$  that filters it. Furthermore, if the FO query

is existential, the result is a USPJ-plan, while if the query is positive existential, the result is a USPJ plan.

PROOF. We create a function  $\mathsf{ToPlan}(\varphi(\vec{x}))$  that returns a plan that filters it. For simplicity, we will assume that formula  $\varphi$  does not contain constants. The definition of ToPlan will be via induction on the structure of  $\varphi$ .

ToPlan(True) will be the plan that just returns  $T_{\vec{x}}$  while ToPlan(x = y) performs a selection on  $T_{\vec{x}}$ .  $\land$  and  $\lor$  will translate to join and union in the usual way.

Consider the formula  $\psi = \exists \vec{y} \ R(\vec{x}, \vec{y}) \land \varphi(\vec{x}, \vec{y}, \vec{z})$ . For the active-domain semantics, it suffices to consider such "relativized quantifications," since a general existential quantification can be broken up into a union of these. Assume for simplicity that  $R(\vec{x}, \vec{y})$  has no repetition of variables. ToPlan( $\psi$ ) will be a plan that takes as input  $T_{\vec{x} \cup \vec{z}}$  with attributes corresponding to  $\vec{x} \cup \vec{z}$  and consists of the concatenation of the following commands:

$$\begin{split} T_1 & \leftarrow_{\mathsf{OutMap}} \mathsf{mt}_R \leftarrow_{\mathsf{InMap}} \pi_{\vec{x}} T_{\vec{x} \cup \vec{z}} \\ T_2 & := T_1 \bowtie T_{\vec{x} \cup \vec{z}} \\ T_3 & := \mathsf{ToPlan}(\varphi) (T_{\vec{x} \cup \vec{y} \cup \vec{z}} := T_2) \\ \mathsf{Return} \, \pi_{\vec{x} \cdot \vec{z}} T_3. \end{split}$$

Here, (1)  $\operatorname{mt}_R$  is any access method on R such that all of its input positions are occupied by an  $x_i$  from  $R(\vec{x}, \vec{y})$ . Such a method exists since  $\varphi$  is executable for membership checks. (2)  $T_3 := \operatorname{ToPlan}(\varphi)(T_{\vec{x} \cup \vec{y} \cup \vec{z}} := T_2)$  is the set of commands in  $\operatorname{ToPlan}(\varphi)$  with the table  $T_2$  substituted for  $T_{\vec{x} \cup \vec{y} \cup \vec{z}}$  and an assignment to  $T_3$  replacing the Return command. (3) InMap maps attribute  $a_{x_i}$  of  $T_{\vec{x} \cup \vec{z}}$  to the position of R containing  $x_i$ . (4) OutMap maps position i of R to attribute  $x_{a_j}$  or  $y_{a_j}$ , where  $x_{a_j}$  or  $y_{a_j}$  is in position i of R in  $R(\vec{x}, \vec{y})$ . The case where variables are repeated is handled by inserting additional middleware query commands that enforce these repetitions.

To compute ToPlan( $\forall \vec{y} \ R(\vec{x}, \vec{y}) \rightarrow \varphi(\vec{x}, \vec{y}, \vec{z})$ ), it suffices to get a plan for its negation  $\exists \vec{y} \ R(\vec{x}, \vec{y}) \land \neg \varphi(\vec{x}, \vec{y}, \vec{z})$ ). Thus, we give a construction for the case of general negation.

ToPlan( $\neg \varphi$ ) returns  $T_{\vec{x}}$  — ToPlan( $\varphi$ ), where  $T_{\vec{x}}$  has attributes corresponding to the free variables of  $\varphi$ . This can be implemented by a plan that first performs the commands in ToPlan( $\varphi$ ), with the output in some table T', and then does a middleware query command subtracting T' from  $T_{\vec{x}}$ . When  $\varphi$  is a relational atom, this can be implemented as a nonmembership check.

The properties of the translation are easily verified.  $\Box$ 

An *executable FO query* will be a query that performs an executable UCQ to get a set of tuples and then filters it using a formula executable for membership checks. Formally, such a query consists of:

- (i) a set  $x_1 \dots x_k$  of variables;
- (i) a first-order formula  $\tau(x_1 \dots x_l)$  using a distinguished relation  $T_{\bar{x}}$ , containing as free variables each  $x_1 \dots x_k$ , whose arity matches the number of free variables in  $\tau$ , with  $\tau$  executable for membership checks; and
- (i) an executable UCQ  $\epsilon(x_1 \dots x_l)$ .

To evaluate an executable FO query on an instance I, we proceed as follows: (1) evaluate  $\epsilon$  over I to get a set of tuples  $I_{\vec{x}}$ , (2) evaluate  $\tau$  over I and  $I_{\vec{x}}$  as the interpretation of  $T_{\vec{x}}$  to get a subset  $I'_{\vec{x}}$  of the tuples in  $I_{\vec{x}}$ , and (3) project  $I'_{\vec{x}}$  on  $x_1 \dots x_k$ . We refer to  $x_1 \dots x_k$  as the *return variables*,  $\epsilon$  as the *output envelope*, and  $\tau$  as the *filter formula*.

**Expressive equivalence.** We now compare the languages we have introduced. From Propositions 3.1 and 3.2 we see the following.

22:14 M. Benedikt et al.

Proposition 3.3. Every executable FO query can be converted into an RA-plan.

We will now explain that, conversely, nested RA-plans can be translated into executable FO queries, and thus the same is true for RA-plans. This will imply that RA-plans, nested RA-plans, and executable FO queries have the same expressiveness. In the electronic appendix, we show:

Theorem 3.4. Nested RA-plans, RA-plans, and executable FO queries have the same expressiveness, and there are computable transformations going from each formalism to an equivalent query in the other.

We also show in the electronic appendix that every USPJ-plan has an equivalent USPJ-query, and hence (by prior results) an equivalent existential formula. We also show, using the results of Deutsch et al. [2007], that the notion captures all existential formulas that have a plan.

### 4. AXIOMATIZING ACCESS PATTERNS

We will now present "proof goals that capture the existence of a plan." That is, we will give a set of axioms and a proof goal using those axioms such that proofs that realize the proof goal can be converted to plans. We will need different proof goals for different kinds of plans. We will start with a proof goal that will correspond to plans that do not use negation, the SPJ-plans.

Given schema Sch, the *forward accessible schema for* Sch, denoted AcSch(Sch), is the schema without any access restrictions, such that:

- —The constants are those of Sch.
- —The relations are those of Sch, a unary relation accessible(x) (x is an accessible value) plus a copy of each relation R of Sch called InfAccR (the inferred accessible version of R).
- —The constraints are those of Sch (referred to as "Sch constraints" later) along with the following constraints:
  - —accessibility axioms: for each access method mt on relation R of arity n with input positions  $j_1 \dots j_m$ , we have a rule:

$$\mathsf{accessible}(x_{j_1}) \land \ldots \land \mathsf{accessible}(x_{j_m}) \land R(x_1 \ldots x_n) \rightarrow \mathsf{InfAcc}R(x_1 \ldots x_n) \land \bigwedge_j \mathsf{accessible}(x_j).$$

In addition, we have accessible(c) for each constant c of Sch.

—A copy of each of the original integrity constraints, with each relation R replaced by InfAccR. We refer to these as "InfAccCopy constraints" later.

Informally, accessible(c) indicates that the value c can be returned by some sequence of accesses. The inferred accessible relations represent facts that can be derived from facts exposed via the access methods using reasoning. Thus, the forward accessible schema represents the rules that allow one to move from a "hidden fact" (e.g.,  $R(c_1 \ldots c_n)$ ) to an inferred accessible fact (e.g.,  $InfAccR(c_1 \ldots c_n)$ ), and from there—using the constraints—to other inferred accessible facts (e.g.,  $InfAccS(c_1 \ldots c_n, d)$  for a new chase constant d, witnessing the right-hand side of a rule firing requiring  $\exists y InfAccS(c_1 \ldots c_n, y)$ . From the structure of the rules, one sees that an InfAccCopy constraint can fire based on facts generated by other kinds of rules, but the firing of an InfAccCopy constraint cannot trigger either accessibility axioms or Sch constraints.

Given a query Q, its *inferred accessible version* InfAccQ is obtained by replacing each relation R by InfAccR. Informally, InfAccQ represents the fact that the existence of a witness to Q can be obtained through making accesses and reasoning.

We will overload AcSch(Sch) to refer to the conjunction of axioms in this schema AcSch(Sch). For a positive existential plan, we will be interested in the following entailment:

$$Q \land \mathsf{AcSch}(\mathsf{Sch}) \models \mathsf{InfAcc}Q.$$

Informally, this means that we can infer from Q holding in a hidden database that Q's truth must be visible to a user via accesses and reasoning with constraints.

*Example 4.1.* Recall the setting of Example 1.3. We had a Profinfo table containing information about faculty, including their last name, office number, and id, with a restricted interface that requires giving an id of an employee as an input. We also had a Udirectory table containing the id and last name of every university employee, with an input-free access method.

We were interested in the query asking for ids of faculty named "Smith." That is:

$$Q = \exists$$
onum Profinfo(eid, onum, "Smith").

In this case, we have

 $InfAccQ = \exists onum InfAccProfinfo(eid, onum, "Smith").$ 

The forward accessible schema includes rules:

- —Profinfo(eid, onum, Iname) → Udirectory(eid, Iname)
- —Udirectory(eid, Iname) → InfAccUdirectory(eid, Iname) ∧ accessible(Iname) ∧ accessible(eid)
- —Profinfo(eid, onum, Iname)  $\land$  accessible(eid)  $\rightarrow$  InfAccProfinfo(eid, onum, Iname)  $\land$  accessible(onum)  $\land$  accessible(Iname)

One can check that Q is contained in InfAccQ w.r.t. AcSch(Sch).

In AcSch(Sch), we only had rules going from the original relations R to InfAccR. Going back to the informal intuition, we can think of this as capturing the positive information revealed in an access, but not the negative information (that a certain tuple is not in the answer). We will later prove that this entailment is equivalent to existence of an SPJ-plan. To capture first-order plans, we should have axioms capturing both positive and negative information returned by accesses. We give such an extension now.

Let AcSch<sup>↔</sup>(Sch) extend the axioms of AcSch(Sch) with the following axioms (universal quantifiers omitted):

$$\bigwedge_{i \leq m} \mathsf{accessible}(x_{j_i}) \land \mathsf{InfAcc}R(x_1 \ldots x_n) \rightarrow R(x_1 \ldots x_n) \land \bigwedge_{i \leq n} \mathsf{accessible}(x_i).$$

Here, R is a relation of Sch having an access method with input positions  $j_1 \dots j_m$ . Notice that these rules are obtained from those of AcSch(Sch) by switching the roles of InfAccR and R, resulting in a rule set where the original schema and the InfAcc copy are treated symmetrically. We will now be interested in the following entailment:

$$Q \wedge \mathsf{AcSch}^{\leftrightarrow}(\mathsf{Sch}) \models \mathsf{InfAcc} Q.$$

We can think informally of AcSch<sup>↔</sup>(Sch) as capturing both positive and negative information revealed from an access.

22:16 M. Benedikt et al.

### 4.1. Statement of the Main Results

We are now ready to state our main results on the relationship between the entailments mentioned before and plans. We will also explain how each entailment is stating a semantic property of the query Q.

**RA-plans and the schema** AcSch<sup>↔</sup>. For RA-plans, our main result is:

THEOREM 4.2. For any conjunctive query Q and access schema Sch with TGD constraints, there is an RA-plan answering Q (over databases in Sch) if and only if  $Q \land \mathsf{AcSch}^{\leftrightarrow}(\mathsf{Sch}) \models \mathsf{InfAcc} Q$ .

Further, from any chase proof witnessing  $Q \land \mathsf{AcSch}^{\leftrightarrow}(\mathsf{Sch}) \models \mathsf{InfAcc}\,Q$ , we can extract (in linear time) an RA-plan for Q over  $\mathsf{Sch}$ .

We now wish to explain the semantic property, which we will denote as *access determinacy*, that corresponds to the proof goal  $Q \land \mathsf{AcSch}^{\leftrightarrow}(\mathsf{Sch}) \models \mathsf{InfAcc}Q$ , and (as we will later show) to the existence of an RA-plan.

Given an instance I for schema Sch the  $accessible\ part\ of\ I$ , denote AccPart(I) consists of all the facts over I that can be obtained by starting with empty relations and iteratively entering values into the access methods. Formally, it is a database containing a set of facts  $AccessedR(v_1\ldots v_n)$ , where R is a relation and  $v_1\ldots v_n$  are values in the domain of I such that  $R(v_1\ldots v_n)$  holds in I, obtained by starting with relations  $AccessedR_0$  and  $AccessedR_0$  and Acces

$$\mathsf{accessible}_{i+1} = \mathsf{accessible}_i \ \cup \bigcup_{\substack{R \text{ a relation} \\ i < \mathit{arity}(R)}} \pi_j(\mathsf{Accessed}R_i)$$

and

$$\mathsf{Accessed} R_{i+1} = \mathsf{Accessed} R_i \cup \bigcup_{\substack{(R,\{j_1,\ldots,j_m\})\\ \text{o method of Sch}}} \{(v_1\ldots v_n) \in I(R) \,|\, \{v_{j_1}\ldots v_{j_m}\} \subseteq \mathsf{accessible}_i\}.$$

Here,  $\pi_j(\mathsf{Accessed}_i(R))$  denotes projection of  $\mathsf{Accessed}_i(R)$  on the  $j^{th}$  position. For finite instances, a fixpoint will be reached after |I| steps, where |I| denotes the number of facts in I. For arbitrary instances, the limit of these instances over all i will be a fixpoint.

We consider AccPart(I) as a database instance for the schema with relations accessible and AccessedR. Later we will sometimes refer to the values in the relation accessible as the *accessible values of I*.

In the case of vocabulary-based access restrictions, the accessible part of an instance just represents the restriction of the instance to the visible relations (e.g., view tables). We now are ready to give the semantic property.

Definition 4.3 (Access Determinacy). Q is said to be access determined over Sch if for all instances I and I' satisfying the constraints of Sch with AccPart(I) = AccPart(I'), we have Q(I) = Q(I').

If a query is *not* access determined, it is obvious that it cannot be answered through any plan, since it is easy to see that any plan can only read tuples from the accessible part. In the case of interface restrictions given by a collection of views, each associated with a view definition, access determinacy just says that for instances of the schema where

 $<sup>^1</sup>$ In the presence of schema constants, we would start with  $accessible_0$  consisting of the schema constants.

the views are evaluated according to their definitions, the query result is a function of the view images. This is the notion of *determinacy* whose study was initiated by Segoufin and Vianu [2005] and Nash et al. [2010].

The following claim relates our entailment hypothesis and this preservation property.

Claim 1. The following are equivalent, for any first-order query Q and any access schema with first-order constraints:

- (1) Q entails InfAccQ with respect to the rules in  $AcSch^{\leftrightarrow}(Sch)$ .
- (2) Q is access determined over Sch.

Proof. For simplicity, we assume Q is a Boolean conjunctive query. The non-Boolean case is a straightforward generalization.

We prove that the first item implies the second. Fix I and I' satisfying the schema with the same accessible part, and assume I satisfies Q. Consider the instance I'' for AcSch $^{\leftrightarrow}$ (Sch) formed by interpreting the relations R as in I, the relation accessible by the accessible values of I, and each InfAccR by the interpretation of R in I'. Then one can easily verify that I'' satisfies the constraints of AcSch $^{\leftrightarrow}$ (Sch).

Since I (and hence I'') satisfies Q and we are assuming that Q entails InfAccQ with respect to  $AcSch^{\leftrightarrow}(Sch)$ , we can conclude that I'' must satisfy InfAccQ. Thus, Q holds in I' as required.

We now argue from the second item to the first, which will complete the proof of the claim. Suppose Q is not contained in InfAccQ with respect to the rules in AcSch $^{\leftrightarrow}$ (Sch). Hence, there is an instance  $I^{AcSch}$  satisfying the rules of AcSch (Sch) and also satisfying  $Q \wedge \neg \mathsf{InfAcc} Q$ . Let  $I_1$  consist of the restriction of  $I^{\mathsf{AcSch}^{\leftrightarrow}}$  to the original schema relations. Let  $I_2$  consist of the inferred accessible relations from  $I^{AcSch}$ , renamed to the original schema. We first claim that a fact  $F = R(e_1 \dots e_n)$  of the accessible part of  $I_1$  is in the accessible part of  $I_2$ . We prove this by induction on the appearance point of F, the lowest i such that F appears in Accessed $R_i$ . Since AccessedR in the accessible part is the union of these relations, a minimal i must exist for each F. F appears in Accessed  $R_i$  due to an access using elements  $e_{j_1} \dots e_{j_m}$  that satisfy accessible facts that had a strictly smaller appearance point. Thus, by induction, these earlier facts are in the accessible part of  $I_2$ , and in particular  $e_{j_1} \dots e_{j_m}$  are accessible values of  $I_2$ . Using the axioms, we have that  $InfAccR(e_1 \dots e_n)$  holds, and thus  $R(e_1 \dots e_n)$  holds in  $I_2$ . Using the definition of accessible part, we conclude that F is in the accessible part of  $I_2$  as required. Arguing symmetrically, we have that  $I_1$  and  $I_2$  have the same accessible part, and hence they contradict access determinacy.  $\Box$ 

Using this claim, we can restate Theorem 4.2:

For any conjunctive query Q and access schema Sch with TGD constraints, there is an RA-plan answering Q (over databases in Sch) if and only if Q entails InfAccQ with respect to the rules in AcSch $^{\leftrightarrow}$ (Sch) if and only if Q is access determined.

Note that in the direction from right to left, we are moving from a preservation property to a syntactic restriction.

We will return to the algorithm that proves Theorem 4.2 later.

SPJ-plans and the schema AcSch. We now state an analogous result for SPJ-plans.

Theorem 4.4. For any conjunctive query Q and access schema Sch with TGD constraints, there is an SPJ-plan answering Q (over instances in Sch) if and only if  $Q \land AcSch(Sch) \models InfAcc Q$ .

Further, for every chase proof witnessing  $Q \land \mathsf{AcSch}(\mathsf{Sch}) \models \mathsf{InfAcc}Q$ , we can extract an SPJ-plan.

We will again translate the entailment into a preservation property of the query Q.

22:18 M. Benedikt et al.

Definition 4.5 (Access Monotonic Determinacy). We say Q is access monotonically determined over Sch if for all instances I and I' satisfying the constraints of Sch with every fact of AccPart(I) contained in AccPart(I') (i.e., AccPart(I) is a subinstance of AccPart(I')),  $Q(I) \subseteq Q(I')$ .

That is, we have weakened the hypothesis of access determinacy to require only containment of facts, not equality. This definition also generalizes one studied by Nash et al. [2010] in the context of constraints associated to view definitions, denoted there as *monotonicity*.

The following claim now relates these notions to our axioms, analogously to Claim 1.

Claim 2. The following are equivalent (for any first-order query Q and access schema with first-order constraints):

- (1) *Q entails* InfAcc*Q with respect to the constraints in* AcSch(Sch).
- (2) Q is access monotonically determined w.r.t. Sch.

PROOF. Again, we assume Q is Boolean for simplicity.

We prove that the first item implies the second, using the same template as in the proof of Claim 1. Fix I and I' satisfying the schema with the same accessible part, and assume I satisfies Q. Consider the instance I'' for the accessible schema formed by interpreting the relations R as in I, accessible by the accessible values of I, and each InfAccR by the interpretation of R in I'. Access monotonicity implies that I'' satisfies the constraints of AcSch(Sch). Since I (and hence I'') satisfies Q, the assumption tells us that I'' must satisfy InfAccQ, and thus Q holds in I' as required.

Arguing from the second item to the first is also analogous. Suppose Q does not imply InfAccQ with respect to the rules in AcSch(Sch). Hence, there is an instance  $I^{\text{AcSch}}$  satisfying the rules of AcSch(Sch) and also satisfying  $Q \land \neg \text{InfAcc}\, Q$ . Let  $I_1$  consist of the restriction of  $I^{\text{AcSch}}$  to the original schema relations. Let  $I_2$  consist of the inferred accessible relations from  $I^{\text{AcSch}}$ , renamed to the original schema. We claim that a fact  $R(e_1 \ldots e_n)$  of the accessible part of  $I_1$  is again in the accessible part of  $I_2$ . This proof is as in Claim 1, since in this part of the argument we only used the "forward accessibility axioms." From this, we can see that  $I_1$  and  $I_2$  witness that Q is not access monotonically determined, which completes the argument.  $\square$ 

Thus, Theorem 4.4 can be restated as:

For any conjunctive query Q and access schema Sch with TGD constraints, there is an SPJ-plan answering Q (over instances in Sch) if and only if Q entails InfAccQ with respect to AcSch(Sch) if and only if Q is access monotonically determined.

*USPJ* **-plans.** We now investigate the situation for *USPJ* -plans. For arbitrary first-order constraints, there can be conjunctive queries that have *USPJ* -plans but that do not have plans without use of negation. For example, consider query (x) and constraints asserting  $R(x) \leftrightarrow A(x) \land \neg B(x)$ , and assume we have input-free access methods on  $\{A, B\}$ . Then there is a USPJ -plan that is equivalent to  $A(x) \land \neg B(x)$ , but there is no SPJ-plan.

In the conference version [Benedikt et al. 2014], we give another variant of the accessible schema that is geared toward USPJ-plans. This variant restricts the "backward accessibility axiom" so that it only applies to facts  $InfAccR(\vec{d})$  with each  $d_1 \dots d_n$  all satisfying accessible. Since this article does not deal with general first-order constraints, we do not give a proof of this result. Instead, we will focus on the TGD case and will show that for these constraints, whenever we can obtain a USPJ-plan, we can actually get an SPJ-plan as well. That is, we prove, assuming Theorem 4.4:

THEOREM 4.6. For any conjunctive query Q and access schema Sch with TGD constraints, if there is a USPJ-plan answering Q w.r.t. Sch, then there is an SPJ-plan answering Q w.r.t. Sch.

Clearly the second item implies the first. Our proof that the second implies the first will make use of the following result:

LEMMA 4.7. For CQ Q and access schema with TGD constraints Sch, if there is a USPJ-plan answering Q, then there is a USPJ-plan answering Q.

Assuming this lemma, Theorem 4.6 will follow from Theorem 4.4, since USPJ-plans are access monotonically determined (since all of their operations are monotone) and Theorem 4.4 states that access monotonically determined queries have SPJ-plans.

Proof of Lemma 4.7. Let PL be a  $USPJ^-$ -plan for Q. Let PL' be obtained from PL simply by dropping all nonmembership tests, that is, eliminating any nonmembership check

$$T' \Leftarrow \mathsf{mt} \Leftarrow \pi_{a_{j_1} \dots a_{j_m}}(T)$$
 
$$T'' \coloneqq T - (T \bowtie T')$$

and replacing any reference to T'' with a reference to T.

A straightforward induction shows that, on all instances I, we have that PL' returns (at least) all tuples returned by PL. Therefore, it suffices to show that, on all instances I satisfying  $\Sigma$ , every tuple **a** returned by PL' is returned also by PL.

We may assume that all occurrences of the union operator in PL are at the top-most level; that is, the only occurrence of union is in a final query middleware command that creates the output table of PL, and the tables  $T_1 \dots T_n$  unioned are formed by disjoint subplans  $PL_i$  of PL. This is argued by the same technique of pulling unions to top level in USPJ queries. The plans  $PL_1 \dots PL_n$  will be called *components* of PL. Likewise, let  $PL'_1, \dots, PL'_n$  be the components of PL'. We see that each  $PL'_i$  is obtained from  $PL_i$  by dropping all nonmembership checks. PL' is a USPJ-plan that returns every tuple of PL. Thus, to prove the lemma, it suffices to show that for any I satisfying the constraints, the output of each  $PL'_i$  on I is contained in the output of  $PL_i$ . Recalling that PL was assumed to answer Q, it is sufficient to show that the output of  $PL_i$  is contained in that of Q. Let  $Q'_i$  be the conjunctive query associated with  $\mathsf{PL}'_i$ . Since  $Q'_i$  and Q are both  $\mathsf{CQs}$ , the completeness of the chase, Theorem 2.1, tells us that to show containment of  $Q_i$  in Q, we must show that in the instance  $\widehat{I}'_i$  formed by chasing the canonical database  $I'_i$  of  $Q'_i$  with the constraints  $\Sigma$ , Q holds onto the tuple  $\mathbf{x}$  corresponding to the free variables of  $Q_i$  in  $I_i'$ .

Let  $Q_i$  be the existential query associated with  $PL_i$  (including all negated atoms). Suppose for any of the negated atoms  $\neg A_i$  of  $Q_i$ ,  $A_j(\mathbf{x})$  held in  $\widehat{I_i}$ . Then, by Theorem 2.1 again,  $Q'_i$  entails that atom relative to the constraints. But then  $PL_i$  would be equivalent to false w.r.t.  $\Sigma$ , and could have been removed from the list of components of PL. Thus, we can assume without loss of generality that the existential query  $Q_i$  holds of  $\mathbf{x}$  in the chase instance  $\widehat{I}'_i$ , as required. Thus, we have shown that Q has a USPJ-plan.  $\square$ 

#### 4.2. Summary

We have now presented a semantic property (access monotonic determinacy) and an entailment (entailment of InfAccQ from Q in the schema AcSch(Sch)), and we have shown they are equivalent. We have also stated a theorem that for TGDs, both of these properties are equivalent to the existence of an SPJ-plan.

22:20 M. Benedikt et al.

Similarly, we have presented the semantic property of access determinacy along with an entailment with respect to AcSch<sup>()</sup>(Sch) and shown they are equivalent, again for arbitrary constraints and queries. We have stated a theorem that these are equivalent to the existence of an RA-plan.

Finally, we have shown, assuming the characterization theorem stated for SPJ-plans earlier, that the existence of a USPJ-plan is equivalent to the existence of an SPJ-plan.

The proofs of the main theorems stated but not proven in this section, Theorem 4.2 and Theorem 4.4, will be given in the next section of the article. While the claims relating entailments and semantic properties in this section held for general first-order constraints, the next section will be focused on TGDs and will use methods specific to them.

Alternative axiomatization of AcSch. Before closing this section, we present a slight alteration of the axiom schema AcSch, denoted AltAccSch, in which the predicate accessible does not appear. This axiomatization will be useful later on, and also gives insight into what the predicate accessible "really" means.

In every forward accessibility axiom, an atom accessible(x) on the left is replaced (in all possible ways) by a relation  $\mathsf{InfAcc}\,R(\vec{z})$ , where  $\vec{z}$  contains x in at least one position (and the other variables are universally quantified), while the occurrences on the right are dropped. For example, the axiom accessible(x)  $\land R(x,y) \to \mathsf{InfAcc}\,R(x,y) \land \mathsf{accessible}(y)$  would be replaced by many axioms, including  $\mathsf{InfAcc}\,R(x,y) \land R(x,y) \to \mathsf{InfAcc}\,R(x,y)$ .

In every backward accessibility axiom, we similarly replace accessible(x) on the left by an atom in the original schema containing x while dropping occurrences on the right.

PROPOSITION 4.8. *Q proves* InfAcc *Q using the axioms of* AcSch $^{\leftrightarrow}$  *if and only if Q proves* InfAcc(Q) *in the modified schema* AltAccSch $^{\leftrightarrow}$ .

PROOF. In one direction, suppose that Q does not prove  $\mathsf{InfAcc} Q$  using the axioms of  $\mathsf{AcSch}^{\leftrightarrow}$ . Then, by Claim 1, Q is not access determined. Fix I and I' instances for the original schema satisfying  $\Sigma$  with the same accessible part but disagreeing on the output of Q. Fix d that is returned by Q in I but not returned by Q in I'. By applying an isomorphism to nonaccessible values of I' and I, we can assume that every nonaccessible value of I' is not in I and vice versa. Let  $I^*$  be the instance for the augmented schema in which relations R are interpreted as in I and relations  $\mathsf{InfAcc} R$  are interpreted as in I'.

We claim that  $I^*$  satisfies AltAccSch $^{\leftrightarrow}$ . Clearly both the original relations and the relations InfAccR satisfy  $\Sigma$ . Consider a modified forward axiom (universal quantifiers omitted):

$$InfAccR_{j_1}(\ldots x_{j_1}\ldots) \wedge \ldots InfAccR_{j_m}(\ldots x_{j_m}\ldots) \wedge R(\vec{x}) \rightarrow InfAccR(\vec{x}),$$

where R has an access method on positions  $j_1 \ldots j_m$ . Suppose we have a tuple  $c_1 \ldots c_m$  in  $I^*$  satisfying the left-hand side of this implication. Then  $c_{j_1} \ldots c_{j_m}$  must be accessible values of I and I'. Since the fact  $R(\vec{c})$  holds in I, it must be in the accessible part of I, and hence in the accessible part of I'. Thus,  $\mathsf{InfAcc}\,R(\vec{c})$  holds in  $I^*$  as required. The backward-accessibility axioms are argued symmetrically.

Clearly, the formula  $Q(\vec{d})$  is true on  $I^*$ , since it is true in I and Q is a formula using the relations in the original schema.  $\vec{d}$  does not satisfy Q in I', and thus does not satisfy the formula obtained by interpreting each relation R by InfAccR in I'. Thus, it cannot be returned by InfAccQ on  $I^*$ .

 $I^*$  therefore is a witness that Q does not prove InfAccQ in  $AltAccSch^{\leftrightarrow}$ .

In the other direction, suppose we have  $I^*$  witnessing that Q does not prove  $\mathsf{InfAcc}(Q)$  in  $\mathsf{AltAccSch}^{\leftrightarrow}$ . Expand  $I^*$  to an instance  $I^+$  for the signature extended with accessible, by interpreting accessible by all values that lie in the domain of some  $\mathsf{InfAcc}R$  relation and in the domain of some relation of the original schema. We claim that the resulting instance satisfies the constraints of  $\mathsf{AcSch}^{\leftrightarrow}$ . The accessibility axioms follow directly from the corresponding axioms of  $\mathsf{AltAccSch}^{\leftrightarrow}$ . Similarly, we see that the output of Q in  $I^+$  is the same as the output of  $I^+$  in  $I^+$  in  $I^+$  is the same as the output of  $I^+$ . Thus, we see that  $I^+$  does not prove  $I^+$  in  $I^+$  in

# 5. ALGORITHMS TRANSFORMING PROOFS TO PLANS

Recall from Section 2.1 that for query containment problems using conjunctive queries and TGDs, we can use the proof system known as the chase. In the chase, a proof can be rephrased as a sequence of database instances, beginning with the canonical database of query Q, evolving by firing rules—that is, grounding the TGDs. By a *full proof* we mean a chase sequence beginning with the canonical database of the source query Q and ending with a configuration having a match for the target query.

We also have seen a collection of proof goals that capture semantic properties of queries, with respect to TGD constraints  $\Sigma$ . These proof goals are all of the form

$$Q \wedge \Gamma \models \mathsf{InfAcc} Q$$
,

where Q is the query we are trying to reformulate, InfAccQ is a query obtained from copying Q on the "inferred accessible" relations, and  $\Gamma$  consists of two copies of  $\Sigma$ —the Sch constraints and InfAccCopy constraints—along with accessibility axioms relating the two copies. In particular, we have a problem of conjunctive query containment with respect to TGD constraints (namely,  $\Gamma$ ), and hence, in seeing whether these properties hold, we can restrict our attention to chase proofs.

We will show that these semantic properties are equivalent to the existence of plans. In each case, we show that from any proof of a proof goal, we can read off a plan. We focus first on the case of *SPJ*-plans and the forward accessible schema AcSch(Sch).

Given a chase sequence  $\mathsf{config}_1 \ldots \mathsf{config}_k$  corresponding to a full proof, let  $C_{\mathsf{SeqConsts}}$  be the set of chase constants generated by firings of Sch constraints within this sequence.

We will convert prefixes of our full proof  $\operatorname{config}_1 \ldots \operatorname{config}_k$  into plans by induction on the number of  $\operatorname{accessibility}$  axioms fired in the prefix. We will generate plans  $\operatorname{PL}_i$  for any prefix  $\operatorname{config}_1 \ldots \operatorname{config}_k$  that ends with the firing of an  $\operatorname{accessibility}$  axiom, where the generated plan  $\operatorname{PL}_i$  will assign tuples to a temporary table  $T_j$  whose attributes correspond to a subset  $C_i$  of  $C_{\operatorname{SeqConsts}}$ . Informally, rows of these tables will store possible homomorphisms that map the chase constants into the instance being queried. Therefore, we interchangeably talk about constants or attributes when referring to the elements of  $C_i$  hereafter. The  $C_i$  will be monotonic under inclusion as i increases. We will maintain as an invariant that the attributes in  $C_i$  are exactly the constants  $c \in C_{\operatorname{SeqConsts}}$  such that  $\operatorname{accessible}(c)$  holds in the configuration of the last element of the sequence.

Our final plan will correspond to the trivial prefix  $config_1 \dots config_k$ .

The induction step for rule firings other than accessibility axioms will append nothing to the plan. In the induction step, we consider a chase sequence ending with the firing of an accessibility axiom:

$$\begin{split} \mathsf{accessible}(c_{j_1}) \wedge \dots \mathsf{accessible}(c_{j_m}) \wedge R(c_1 \dots c_n) \\ &\to \mathsf{InfAcc} R(c_1 \dots c_n) \wedge \bigwedge_j \mathsf{accessible}(c_j) \end{split}$$

22:22 M. Benedikt et al.

associated with method mt on relation R having input positions  $j_1 \dots j_m$ . We say that the rule firing exposes fact  $R(c_1 \dots c_n)$ . Let  $\operatorname{config}_{i-1}$  be the chase configuration prior to the firing of this rule. Note that by the inductive invariant, each  $c_{j_1} \dots c_{j_m}$  must be an attribute of table  $T_{i-1}$  associated to the sequence prior to the firing. We will define the commands that correspond to this rule firing.

We will explain the induction step first in the case where none of  $c_{j_1} \dots c_{j_m}$  are schema constants and no constant is repeated in  $R(c_1 \dots c_n)$ . We defer the additional cases until the next subsection. We first generate an access command whose input expression is the projection of  $T_{i-1}$  onto  $c_{j_1} \dots c_{j_m}$ , with the input mapping InMap taking columns  $c_{j_1} \dots c_{j_m}$  of  $T_{i-1}$  to input positions  $j_1 \dots j_m$  of mt. The command's output will be a table  $T_i'$  with attributes  $C_i = C_{i-1} \cup \{c_1 \dots c_n\}$ , with the output mapping taking position d to  $c_d$ . We follow the access command by a middleware query command that sets  $T_i$  to the join of  $T_i'$  with  $T_{i-1}$ .

If we have a full chase proof, the final configuration must have a match for InfAcc Q. Let V be the set of chase constants corresponding to the free variables of Q. We add a last Return command that will return the projection of  $T_i$  on V. In the special case that Q is Boolean, the final query amounts to checking that the table  $T_i$  is nonempty.

# ALGORITHM 1: Chase-Proof-to-SPJ-Plan Algorithm

```
1 Input: full chase proof with configurations config<sub>1</sub>...config<sub>k</sub>
 2 V = attributes for free variables of Q;
 3 Plan := \emptyset;
 4 T_0 = table with no columns;
 5 numsteps = 0;
 6 for i = 1 to k do
        if config<sub>i</sub> is obtained by firing an accessible axiom exposing fact F = R(c_1 \dots c_n) via
 7
        method mt with inputs j_1 \dots j_m then
             Append to Plan command T_i' \leftarrow \mathsf{mt} \leftarrow \pi_{c_{j_1} \dots c_{j_m}}(T_{i-1});
 8
             Append to Plan command T_i = T'_i \bowtie T_{i-1};
 9
10
            numsteps + +
11 Add command "Return \pi_V(T_{numsteps})" to plan;
12 Return Plan
```

*Example* 5.1. Consider a variant of Example 1.3, using the same schema and the query  $Q = \exists \text{eid} \exists \text{onum} \exists \text{lname Profinfo(eid, onum, lname)}$ . Using the chase, we get the following **proof**:

- (1) Create the canonical database containing the single fact  $\{Profinfo(eid_0, onum_0, lname_0)\}$
- (2) One of the initial integrity constraints matches Profinfo(eid<sub>0</sub>, onum<sub>0</sub>, lname<sub>0</sub>), and firing the rule infers Udirect(eid<sub>0</sub>, lname<sub>0</sub>).
- (3)  $Udirect(eid_0, Iname_0)$  matches an accessibility axiom, and the rule firing generates  $InfAccUdirect(eid_0, Iname_0)$  and  $accessible(eid_0)$ .
- (4) An accessibility axiom matches Profinfo(eid<sub>0</sub>, onum<sub>0</sub>, lname<sub>0</sub>) ∧ accessible(eid<sub>0</sub>), creating fact InfAccProfinfo(eid<sub>0</sub>, onum<sub>0</sub>, lname<sub>0</sub>).
- (5) We now have a match for InfAccQ, so we have a successful proof.

# Here is the generated **plan**:

(1) The firing of the accessibility axiom in the third step previously generates access command  $T_1 \Leftarrow \mathsf{mt}_{\mathsf{Udirect}} \Leftarrow \emptyset$ , where  $T_1$  is a table with attributes for  $\mathsf{eid}_0$  and  $\mathsf{Iname}_0$ .

- (2) The accessibility axiom on the fourth line generates commands  $T_2 \Leftarrow \mathsf{mt}_{\mathsf{Profinfo}} \Leftarrow \pi_{\mathsf{eid}_0} T_1$  and  $T_2 := T_2 \bowtie T_1$ .
- (3) The match at the end generates the command output  $\pi_{\emptyset}(T_2)$ , which returns nonempty if  $T_2$  is nonempty.

That is, we do an input-free access on Udirect and put all the results into Profinfo.

# 5.1. Full Definition of SPJ-Plan Generation Algorithm

In the first presentation of the algorithm, we did not deal with several "corner cases" concerning these rule firings:

- —The fact  $F = R(c_1 \dots c_n)$  may contain not only constants that are produced in the chase proof ("chase constants") but also constants from the schema (e.g., "Smith", 3, etc.).
- —The fact may have some chase constants repeated.

Here we complete the description to cover these cases.

We first discuss schema constants and repetition of chase constants in *input positions*. If  $R(c_1 \ldots c_n)$  has some chase constants repeated in an input position and possibly some of  $c_{j_1} \ldots c_{j_m}$  are schema constants, then in our input expression we perform a projection of  $T_{i-1}$  onto the attributes corresponding to the distinct chase constants in  $c_{j_1} \ldots c_{j_m}$  and then transform every tuple t into a corresponding tuple t' that can be used as an input to the access method mt. We do this transformation by repeating values or filling in positions with constants, using  $R(c_1 \ldots c_n)$  as a template. That is, if  $j_i$  is such that  $c_{j_i}$  is a chase constant c, then set  $t'_{j_i}$  to be c, while if  $c_{j_i}$  is a schema constant d, then set  $t'_{j_i}$  to be d. This transformation can be done with an SPJ query.

Example 5.2. Consider an accessibility axiom rule firing at step j of the form

accessible(
$$c_1$$
)  $\land$  accessible("Smith")  $\land$   $R(c_1, c_1,$  "Smith",  $c_2, c_2,$  "Jones")  $\rightarrow$  InfAcc $R(c_1, c_1,$  "Smith",  $c_2, c_2,$  "Jones").

Suppose that this rule firing was associated with access method m on R having inputs on the first three positions of R. Note that the axioms guarantee that schema constants like "Smith" are always in accessible.

If  $T_{i-1}$  is the temporary table produced by the commands associated with the  $i-1^{th}$  firing, then  $T_{i-1}$  will have an attribute for  $c_1$ . We create an SPJ expression  $E_i$  that will take as input  $T_{i-1}$  and produce a table  $T_i$  with

$$\{(c_1=v_1,c_1'=v_1,c_{\text{``Smith''}}=\text{``Smith''})|v_1\in\pi_{c_1}(T_{i-1})\}.$$

Such an  $E_i$  can be expressed using projection, a self-join, and a constant operator. We then generate an access command to mt using  $E_i$  as input.

The modification of the algorithm that deals with repetition and schema constants in *output positions* (i.e., noninput positions of the accessed relation) is similar, being done by postprocessing, using a middleware query command to filter the output table down to those tuples that have constants in the proper positions and repeated values as found in the fact F. We then apply a projection to obtain a table whose attributes are the distinct chase constants in F.

Example 5.3. In the case of Example 5.2, the output table  $T_i'$  of the access command could have attributes  $c_1, c_1', c_{\mathsf{Smith}}, c_2, c_2', c_{\mathsf{Jones}}$ , and the output mapping would map the positions of R to these attributes. We then postprocess by performing the middleware query command  $T_i'' = \pi_{c_1,c_2} \sigma_{c_2 = c_2' \wedge c_{\mathsf{Jones}}} "T_i'$ .

22:24 M. Benedikt et al.

## 5.2. Properties of SPJ-Plan Generation and Proof of Theorem 4.4

We will now show that the prior algorithm proves Theorem 4.4: it takes any chase proof and produces an SPJ-plan that answers Q.

That is, we will prove:

PROPOSITION 5.4. For every chase proof  $\operatorname{config}_1 \ldots \operatorname{config}_k$  proving  $\operatorname{InfAcc}Q$  from Q, the corresponding plan  $\operatorname{PL}$  generated by Algorithm 1 answers Q.

If config<sub>i</sub> denotes the  $i^{th}$  configuration in the chase proof, then let InfAccQuery(config<sub>i</sub>) be the conjunctive query formed by taking the conjunction of all facts of the form InfAcc $R(\vec{c})$  in config<sub>i</sub> and turning them into an existentially quantified conjunction of facts  $R(\vec{w})$ , changing the chase constants c that satisfy accessible(c) to free variables and the other chase constants to existentially quantified variables. Note that if config<sub>i</sub> has a match for InfAccQ, then InfAccQuery(config<sub>i</sub>) entails Q. Recall that our algorithm generated commands for every firing of an accessibility axiom, producing a corresponding plan  $PL^i$ , which produces a temporary table  $T_i$ . The attributes of  $T_i$  will be all chase constants in the interpretation of accessible within config<sub>i</sub>—hence, these match the output attributes of InfAccQuery(config<sub>i</sub>).

Given an instance I, a mapping from the chase constants present in the chase configuration  $\operatorname{config}_i$  produced by the  $i^{th}$  step of the algorithm to I that preserves all facts in  $\operatorname{config}_i$  within the original schema will be called a  $\operatorname{Sch}$   $\operatorname{config}_i$ -tuple of I. As the notation implies, we will consider such elements as tuples with attributes from the constants of  $\operatorname{config}_i$ .

We let  $T_i(I)$  be the instance of table  $T_i$  produced by the plan  $PL^i$  when run on an instance I of schema Sch. Although the notation omits the dependence on  $PL^i$ , the value of  $T_i$  in  $PL^j$ , whenever it is well defined, is independent of j.

We claim that the following "universality properties" hold for any instance *I* of Sch:

- —For every Sch config<sub>i</sub>-tuple of I, its projection on to those constants of config<sub>i</sub> satisfying accessible is in  $T_i(I)$ .
- $-T_i(I)$  is a subset of the tuples in InfAccQuery(config<sub>i</sub>)(I).

We explain why these two assertions together imply Proposition 5.4. First, consider a tuple t returned by Q on a database instance I satisfying the Sch integrity constraints. I can be extended, just via duplicating its relations, to an instance  $I^*$  satisfying the accessible schema AcSch(Sch). Since t is returned by Q, there is a homomorphism  $h_1$  of the canonical database of Q to t. In  $I^*$ , we can mimic each rule firing that produced the facts of  $\operatorname{config}_i$ , and thus for each t, we can extend t to a mapping t that preserves all facts of t config; Restating in the terminology of this section, for each t config; we can extend t to a Sch t config; tuple t. Now by the first assertion previously, the projection of t on the constants satisfying accessible is in t conversely, in particular, t, the projection of t onto the constants corresponding to free variables of t in the projection of t onto the final result of the top-level plan generated by the algorithm. Conversely, consider that for the final configuration t in the projection of t in the projection of t in the projection of t in the final configuration t in the projection of t in the projection of t in the final configuration t in the projection of t in t

The previous two assertions are proven by induction on i.

We consider the inductive step for both assertions corresponding to an application of an accessibility axiom. We first give the argument for the basic version of the algorithm, ignoring repetition of variables and schema constants, and then discuss how to extend to incorporate the full version.

We consider the inductive case for firing on an accessibility axiom. Fix a Sch config<sub>i</sub>-tuple t and let  $t_i$  be its projection on the constants satisfying the predicate accessible. By

induction, the projection of t on the accessible constants of  $\operatorname{config}_{i-1}$  is in  $T_{i-1}(I)$ . In the absence of repetition of variables and constants, we know  $T_i(I)$  is formed from  $T_{i-1}(I)$  by "joining on the access": projecting tuples in  $T_{i-1}(I)$  on the attributes corresponding to inputs to the access, performing the access, and joining the corresponding outputs to  $T_{i-1}(I)$ . We need to show that t extends some tuple returned by this join.

Assume that the accessibility axiom fired in the inductive step was associated with the exposure of some fact  $R(c_1 \ldots c_n)$ , where  $c_{j_1} \ldots c_{j_m}$  satisfied accessible relations in the chase sequence up that point. Let  $t_{\mathsf{Inp}}$  be the projection of t on these input attributes, and t' be the projection on all the  $c_1 \ldots c_n$ . We claim that t' would be returned by an access on mt using  $t_{\mathsf{Inp}}$ . This is clear, since for the corresponding accessibility axiom to fire,  $R(c_1 \ldots c_n)$  must hold in  $\mathsf{config}_{i-1}$ , and thus the  $c_1 \ldots c_n$  attributes of a Sch  $\mathsf{config}_i$ -tuple like t must satisfy t in t.

This completes the argument for the first assertion in the inductive case for firing an accessibility axiom, the argument under the assumption of no repetition of variables and no schema constants. In the general case, we let  $t_{\rm lnp}$  be formed from t as earlier, but incorporating selections and repetition of variables on the input positions corresponding to the fact being exposed. Let t' be formed by taking a tuple in the accessed relation R consistent with  $t_{\rm lnp}$  and applying operations enforcing repetitions and constants in the output positions. We again see that t' would be returned by the preprocessing, method access, and postprocessing operations generated in the inductive step of the algorithm. This is because t is a Sch config<sub>i</sub>-tuple and the corresponding fact added in config<sub>i</sub> must have obeyed these selections in order for the corresponding accessibility axiom to fire.

We now turn to verifying the second assertion in the inductive case for the firing of an accessibility axiom. Consider an arbitrary database instance I satisfying the constraints of the schema, and let  $t_i$  be a tuple of  $T_i(I)$ . We show that  $t_i$  is returned by InfAccQuery(config<sub>i</sub>).

InfAccQuery(config<sub>i</sub>) is an existentially quantified conjunction. By induction, we know that  $t_{i-1}$ , the projection of  $t_i$  on the accessible constants of  $\operatorname{config}_{i-1}$ , satisfies InfAccQuery(config<sub>i-1</sub>), since  $t_{i-1}$  must be in  $T_{i-1}(I)$ . We consider the first interesting "new" conjunct being added at this stage, corresponding to the fact produced by the firing of an accessibility axiom. We first consider the basic case of the algorithm, with no repetition of variables or schema constants. In this case, the axiom firing is of the form

$$\mathsf{accessible}(c_{j_1}) \wedge \dots \mathsf{accessible}(c_{j_m}) \wedge R(c_1 \dots c_n) \to \\ \mathsf{InfAcc}R(c_1 \dots c_n) \wedge \bigwedge_j \mathsf{accessible}(c_j).$$

Recall that the access command produced by this rule firing would be

$$T_i' \Leftarrow \mathsf{mt} \Leftarrow \pi_{\{c_{j_1} \dots c_{j_m}\}}(T_{i-1}),$$

where mt is an access method on R with input positions  $j_1 \dots j_m$ . To obtain  $T_i(I)$ , we joined  $T'_i$  with  $T_{i-1}$ .

Thus, since  $t_i$  is in  $T_i(I)$ , its projection to  $\{c_1 \dots c_n\}$  must satisfy R. Therefore, the atom corresponding to  $R(c_1 \dots c_n)$  in  $\mathsf{InfAccQuery}(\mathsf{config}_i)$  is satisfied by  $t_i$ . Thus, we have proved the second assertion in the inductive step for an accessibility axiom, for the simplified version of the algorithm.

In the general case with constants and repetition, the argument is similar, but we argue that the pre- and post-postprocessing operations guarantee that  $t_i$  must reflect the repetitions and schema constants present in the fact exposed by the access.

22:26 M. Benedikt et al.

We now turn to the inductive cases corresponding to the firing of Sch and InfAccCopy rules. Note that the first assertion is preserved by these rules, since the set of Sch config<sub>i</sub>-tuples can only become smaller or stay the same, as we are required to preserve more facts.

For the second assertion, there is nothing to prove when a Sch rule is fired. In an inductive step for the InfAccCopy constraint rules, conjuncts are added to  $InfAccQuery(config_i)$ . These can easily be seen to hold because the instance I satisfies the integrity constraints of the schema.

This finishes the proof of the second assertion. It also completes the proof of Proposition 5.4.

We are now ready to give the proof of Theorem 4.4.

In one direction, suppose we have an SPJ-plan that answers query Q with respect to the constraints in Sch. Since SPJ-plans are monotone in the accessible data, Q is monotonically access determined. Thus, by Claim 2, Q entails InfAccQ with respect to the constraints in AcSch(Sch). By completeness of chase proofs, this means that there is a chase proof.

In the other direction, suppose that Q entails InfAccQ with respect to the constraints in AcSch(Sch). By completeness of the chase proof, we have a chase proof witnessing this. By Proposition 5.4, Algorithm 1 produces an SPJ-plan that answers Q.

This completes the proof of Theorem 4.4.

### 5.3. RA-Plans for Schemas with TGDs

We have proven Theorem 4.4 by giving a proof-to-plan algorithm that takes a proof that query Q is access monotonically determined and produces an SPJ-plan. One can show that there are conjunctive queries and TGD constraints for which there is an RA-plan but no USPJ-plan. In fact, Nash et al. [2010] shows that even in the case of constraints that define conjunctive query views, there are conjunctive queries that have reformulations over the views, but the reformulations require the relational difference operator. We will discuss a witness of this in Example 5.5 in the next section.

From this, it follows that there are access schemas with TGD constraints and conjunctive queries that have RA-plans over the schema but no SPJ-plans. We now turn to devising an algorithm that proves Theorem 4.2, taking as input a chase proof using  $AcSch^{\leftrightarrow}(Sch)$ , thus "proving that Q is access determined," and outputting an RA-plan.

For ease of exposition, we assume that our constraints contain no constants from the schema, and that our queries and constraints contain no repeated variables in atoms. Thus, the chase proofs will not produce any configurations that contain such facts. The algorithm is generalized to the case where constants are present and there is repetition along the same lines as the algorithm for SPJ-plans, by introducing preand postprocessing middleware query commands around access commands.

**Algorithm description.** Our algorithm will proceed not by forward induction on proofs, as was the case with SPJ-plan generation, but by a backward induction. The algorithm takes as input a suffix  $\operatorname{config}_i \ldots \operatorname{config}_j$  of a full proof consisting of chase configurations  $\operatorname{config}_1 \ldots \operatorname{config}_j$  and produces a nested plan  $\operatorname{PL}_i$ , where nested plans are as defined in Section 3. The plan  $\operatorname{PL}_i$  generated from suffix  $\operatorname{config}_i \ldots \operatorname{config}_j$  will include a distinguished temporary table  $T_{\bar{x}^i}$  with attributes  $\bar{x}^i$  that are the accessible chase constants in  $\operatorname{config}_i$ , denoted accessible( $\operatorname{config}_i$ ): those that satisfy the predicate accessible in  $\operatorname{config}_i$ . In the further inductive steps,  $\operatorname{PL}_i$  will only be used in subplan calls with  $T_{\bar{x}^i}$  being the table substituted. We will thus write  $\operatorname{PL}_i(\bar{x}_i)$  to indicate that  $\operatorname{PL}_i$  is a nested plan with distinguished table  $T_{\bar{x}^i}$ , referring to  $T_{\bar{x}^i}$  as the parameter table of the plan, and  $\bar{x}^i$  as the parameters.

- For Sch or InfAccCopy constraints, the algorithm just returns  $\mathsf{PL}_{i+1}$ . Note that  $\mathsf{accessible}(\mathsf{config}_i) = \mathsf{accessible}(\mathsf{config}_{i+1})$  in this case.
- We consider a suffix  $\operatorname{config}_i$  ...  $\operatorname{config}_j$  where the transition from  $\operatorname{config}_i$  to  $\operatorname{config}_{i+1}$  is formed via a forward accessibility axiom firing via access mt exposing fact  $R(\vec{c})$ . We will generate the nested plan:

$$\begin{split} T_0^{i+1} & \Leftarrow \mathsf{mt} \Leftarrow \pi_{c_{j_1} \dots c_{j_m}} T_{\vec{x}^i} \\ T_1^{i+1} & \coloneqq T_0^{i+1} \bowtie T_{\vec{x}^i} \\ T_{i+1} & \Leftarrow \mathsf{PL}_{i+1}[T_{\vec{x}^{i+1}}] \Leftarrow T_1^{i+1} \end{split}$$
 Return  $\pi_{\mathsf{Free}(Q) \cup \mathsf{accessible}(\mathsf{config.})} T_{i+1}$ 

— We now consider a suffix  $\operatorname{config}_i \ldots \operatorname{config}_j$  where the transition from  $\operatorname{config}_i$  to  $\operatorname{config}_{i+1}$  is formed via a backward accessibility axiom firing exposing fact  $\operatorname{InfAcc} R(\vec{c})$ . We will generate a plan the differs from the plan in the forward case by replacing the last line by commands returning empty if  $T_0^{i+1}$  is empty, and otherwise returning:

$$\{\vec{u} \in \pi_{\mathsf{Free}(Q) \cup \mathsf{accessible}(\mathsf{config}_i)}(T_{i+1}) \mid \ \exists \vec{t} \in T_{\vec{x}^i} \\ \vec{u} \in \bigcap_{\vec{w} \in T_1^{i+1} \pi_{\vec{x}^i} \vec{w} = \vec{t}} \pi_{\mathsf{Free}(Q) \cup \mathsf{accessible}(\mathsf{config}_i)}(\{\vec{z} \in T_{i+1} \mid \ \pi_{\mathsf{accessible}(\mathsf{config}_{i+1})} \vec{z} = \vec{w}\})\}$$

Although we have written the last expression in a mixture of relational algebra and logic, the generation of the last expression from  $T_{i+1}$  and  $T_1^{i+1}$  can be performed in relational algebra.

Fig. 1. Pseudo-code for generating RA-plans for schemas with TGDs.

The output of the plan  $PL_i$  will be a table having attributes for chase constants that either are in accessible(config<sub>i</sub>) or that correspond to free variables of the query.

The algorithm proceeds by downward induction on i.

If j = i (so only one configuration in the proof suffix), the algorithm produces the single command Return  $T_{\bar{x}^j}$ . Note that in this case, accessible(config<sub>j</sub>) must already contain the free variables of Q.

The pseudo-code for the inductive cases of the algorithm is listed in Figure 1. We can verify that the algorithm indeed returns tuples with attributes for all accessible(config $_i$ )  $\cup$  Free(Q)-constants. Thus, for a full proof, the output will have attributes corresponding to the free variables of the query Q. For a full proof, the set of parameters  $\vec{x}^1$  is empty, since no attributes in the initial configuration satisfy accessible. We take the top-level output of our plan generation algorithm to be the result of substituting for the parameter table the singleton instance with only the empty tuple. We denote this instance by  $\emptyset$  later. Thus, when the input is the maximal suffix consisting of a full proof starting from the canonical database of a query Q, we will produce an ordinary relational algebra plan without reference to  $T_{\vec{x}^1}$ , and one whose output constants will be exactly the free variables of Q.

We now give some intuition for the previous steps. In the case of a forward-accessibility axiom, we generate a nested plan that, given an instance of the parameter table  $T_{\vec{x}^i}$  consisting of a single tuple  $\vec{t}$ , acts as follows: it does an access to R using the projection of  $\vec{t}$  to the chase constants  $c_{j_1} \dots c_{j_m}$ . For each result tuple  $\vec{w}$  that joins with  $\vec{t}$ , the plan calls  $\mathsf{PL}_{i+1}(\vec{w} \bowtie \vec{t})$ , where the join is on the common attributes, and projects the results back to the constants in accessible(config<sub>i</sub>)  $\cup$  Free(Q). Finally, the plan returns the union of all of these projections.

22:28 M. Benedikt et al.

In the step for the backward-accessibility axiom, our goal is to generate a plan that is similar, but performing an intersection rather than a union. That is, our plan should behave as follows, given an instance of  $T_{\vec{x}^i}$  consisting of a single tuple  $\vec{t}$ : it does an access to R using the projection of  $\vec{t}$  to the chase constants  $c_{j_1} \dots c_{j_m}$ , then returns the intersection of the projections of the sets  $\mathsf{PL}_{i+1}(\vec{w} \bowtie t)$  to the constants in accessible(config<sub>i</sub>)  $\cup$  Free(Q), where  $\vec{w}$  ranges over tuples in the result that join with t. We define the intersection to be empty if there are no such tuples.

In the Online Appendix, we will show that the nested plan generated by the algorithm answers the query Q. By Theorem 3.4, we can "flatten" the output to an ordinary RA-plan.

We can now complete the proof of Theorem 4.2, using the same argument as in Theorem 4.4. If Q has an RA-plan, then it is access determined, and Claim 1 implies that Q entails InfAccQ with respect to AcSch $^{\leftrightarrow}$ (Sch). In the other direction, if the entailment holds, we get an RA-plan that answers Q using the algorithm described earlier.

*Example* 5.5. We consider a variant of an example due to Afrati [2011]. Our base signature consists of a binary relation R.

We have views  $V_3$  storing the set of pairs of nodes connected by a path of length 3, and  $V_4$  storing the set of pairs connected by a path of length 4.

That is, we have constraints that are universal quantifications of the following rules, which give definitions for the view tables:

$$V_{3}(x, y) \rightarrow \exists x_{2} \exists x_{3} R(x, x_{2}) \land R(x_{2}, x_{3}) \land R(x_{3}, y)$$

$$R(x, x_{2}) \land R(x_{2}, x_{3}) \land R(x_{3}, y) \rightarrow V_{3}(x, y)$$

$$V_{4}(x, y) \rightarrow \exists x_{2} \exists x_{3} \exists x_{4} R(x, x_{2}) \land R(x_{2}, x_{3}) \land R(x_{3}, x_{4}) \land R(x_{4}, y)$$

$$R(x, x_{2}) \land R(x_{2}, x_{3}) \land R(x_{3}, x_{4}) \land R(x_{4}, y) \rightarrow V_{4}(x, y).$$

Our query Q asks for all pairs  $x_1$ ,  $x_6$  such that  $x_1$  reaches  $x_6$  via a path of length 5. Afrati showed that Q can be rewritten over the views as

$$\exists y_5 [V_4(x_1, y_5) \land \forall y_2 V_3(y_2, y_5) \rightarrow V_4(y_2, x_6)].$$

Afrati also argued that Q is not monotone in the views: we can have two instances such that for each view table, the second instance has all the facts of the first instance, but the query result over the second instance does not contain the query result over the first. Hence, there cannot be any USPJ-plan.

Consider an access schema having the constraints listed previously, with the view relations having input-free access and the base tables having no access. We can derive an RA-plan equivalent to the previous rewriting through our proof-based method.

The proof begins with the canonical database of query *Q*:

$$C_1 = \{R(x_1, x_2), R(x_2, x_3), R(x_3, x_4), R(x_4, x_5), R(x_5, x_6)\}.$$

We then apply a chase step with the last constraint earlier, one part of the definition of  $V_4$ , obtaining configuration  $C_2$ , which adds the fact:

$$V_4(x_1, x_5)$$
.

We can now apply a "forward-accessibility axiom" to obtain a configuration  $C_3$  with the additional fact:

InfAcc
$$V_4(x_1, x_5)$$
.

We can now apply the copy of the third constraint earlier, to obtain configuration  $C_4$ , adding additional facts:

$$InfAccR(x_1, z_2), InfAccR(z_2, z_3), InfAccR(z_3, z_4), InfAccR(z_4, x_5).$$

From this we can apply the copy of the second constraint to obtain configuration  $C_5$ , adding fact:

$$InfAccV_3(z_2, x_5)$$
.

Applying a "backward-accessibility axiom," we obtain configuration  $C_6$  with the fact:

$$V_3(z_2, x_5)$$
.

And then applying a chase step with the first constraint earlier leads to configuration  $C_7$ , adding facts:

$$R(z_2, w_3), R(w_3, w_4), R(w_4, x_5).$$

We can then apply the last constraint to get to configuration  $C_8$ , adding fact:

$$V_4(z_2, x_6)$$
.

After this we can apply another "forward-accessibility axiom" to obtain configuration  $C_9$ , adding fact:

$$InfAccV_4(z_2, x_6)$$
.

Finally, we apply a copy of the third constraint, reaching configuration  $C_{10}$  with additional facts:

$$\mathsf{InfAcc} R(z_2,q_3), \mathsf{InfAcc} R(q_3,q_4), \mathsf{InfAcc} R(q_4,q_5), \mathsf{InfAcc} R(q_5,x_6).$$

We now have a match for InfAcc Q.

Applying the proof-to-nested-RA-plan algorithm, we will find that it generates a nested RA-plan that corresponds to this rewriting. We give the interesting steps in the inductive construction, ignoring steps that only call the next inductively defined program.

- —From the final configuration  $C_{10}$ , we generate a plan  $P_{10}$  that takes as input a table with tuples having values for  $x_1, x_5, x_6$ , and  $z_2$  and simply returns the table.
- —From the suffix of the proof beginning at configuration  $C_8$ , we generate  $P_8$ , which takes a table  $T_{x_1,z_2,x_5}$  and performs an access on  $V_4$ , naming the output results  $z_2, x_6$  and joining them with  $T_{x_1,z_2,x_5}$ , returning a table with all joined tuples with attributes  $x_1, x_5, x_6$  and  $z_2$ .
- —From the suffix beginning with configuration  $C_5$ , we generate a plan  $P_5$  that takes as input a table with tuples having attributes  $x_1$  and  $x_5$ .  $P_5$  performs an access on  $V_3$  and selects all tuples  $(z_2, x_5)$  matching the input value for  $x_5$ , calls  $P_8$  on each corresponding  $x_1, z_2, x_5$ , and intersects the projection of the results to  $x_1, x_5, x_6$ .

Thus,  $P_5(x_1, x_5)$  returns  $\bigcap_{z_2|V_3(z_2, x_5)} \{x_1, x_5, x_6|V_4(z_2, x_6)\}.$ 

—From the suffix beginning with configuration  $C_2$ , we generate  $P_2$  that has no input parameters.  $P_2$  performs an access to  $V_4$ , calls  $P_5$  on all the resulting tuples  $x_1, x_5$ , and then unions the projection of the results on to  $x_1, x_6$ .

The plan  $P_1$  returned as the top-level result of the algorithm will be equal to  $P_2$ .

### 5.4. Finite Instances and Tame Constraints

Our results have provided a characterization of when a query can be answered (relative to TGD constraints) over all instances, in terms of proofs of certain entailments. We have also provided a procedure that converts a proof to a plan that answers the query over all instances. It is easy to show that these proof-based characterizations do not hold when the plans are required only to be correct over finite instances.

We will show that for "tame" constraint classes, answerability over all instances and answerability over finite instances coincide, and in particular the characterization 22:30 M. Benedikt et al.

theorems and algorithms relating answerability to entailment still hold in the finite. We also show that the existence of a plan of the appropriate type is decidable. Our proof-to-plan algorithms do not suffice to show this, since they depend on having already found an appropriate proof.

We will first show these results later for constraints given by GTGDs. Recall from Section 2 that these are TGDs where all the variables occurring on the left appear in a single atom of the left. We will show that similar results hold for constraints that satisfy chase termination, such as the weakly acyclic constraints of Deutsch et al. [2008]. Indeed, such results will hold for constraints in other fragments of first-order logic that have the finite model property, such as the Guarded Negation Fragment [Bárány et al. 2011].

THEOREM 5.6. Let Sch be a schema whose constraints are GTGDs and let Q be a conjunctive query. Then, if PL is a USPJ-plan that answers Q over finite instances, then PL answers Q over all instances.

PROOF. We first give the argument when Q is a Boolean query. Fix the USPJ-plan PL for Q. Clearly, there is a USPJ query that holds true on an instance exactly when PL does. Consider the following assertion: for every instance I satisfying the constraints of Sch, I satisfies the query given by PL if and only if it satisfies the query Q. The property is a pair of query containments of conjunctive queries with respect to GTGD constraints. Results of Bárány et al. [2010] imply that such containments have a decidable satisfiability property and have the finite model property:

if such a containment holds on all finite instances, it holds on all instances.

Hence, PL answers Q over all instances.

The extension to the non-Boolean case can be done by converting the free variables of Q into constants.  $\Box$ 

Note that Theorem 5.6 implies that statements made about our proof-to-plan algorithms for SPJ plans over constraints consisting of GTGDs or TGDs with terminating chase within this article still hold if plans are only required to answer a query over finite instances.

In the case of RA-plans, the situation is more complex. First, the analog of Theorem 5.6 fails: we cannot say that for any RA-plan PL that answers a query Q over finite instances, PL answers it over all instances. For example, an RA-plan may return true on all finite instances (and hence answer a tautological query Q) but return false on some infinite instance. However, for GTGDs, we can transfer between the existence of an RA-plan over finite instances and the existence of arbitrary instances, and can still decide if this property holds.

Theorem 5.7. Let Sch be a schema whose constraints are GTGDs and let Q be a conjunctive query. Then there is an RA-plan that answers Q over finite instances if and only if there is an RA-plan that answers Q over all instances. Furthermore, we can decide whether this property holds.

PROOF. Suppose that Q has an RA-plan that works over finite instances, consisting of k access commands. Consider the following property of two instances I and I' for schema Sch: I and I' both satisfy the constraints of the schema and they agree on every fact that can be extracted via at most k successive accesses (k iterations of the fixpoint process used to generate the accessible part), but they disagree on the truth value of  $Q(\vec{c})$  for some  $\vec{c}$ .

The property can be expressed as a Boolean combination of conjunctive queries and GTGD constraints. But it is easy to see that the output of a plan consisting of k access command depends only on the data that can be returned by k iterations of the fixpoint.

Thus,  $\gamma$  has no finite instance satisfying it. Since  $\gamma$  is unsatisfiable over finite instances, it is unsatisfiable over all instances (by Bárány et al. [2010] again). Hence, Q is access determined over all instances. From Claim 1, we conclude that Q entails InfAccQ over all instances, and hence by Theorem 4.2, Q has an RA-plan over all instances.

Decidability follows since whether Q entails InfAccQ over all instances is a containment between CQs with respect to GTGD constraints, and hence decidable by the results of Bárány et al. [2010].  $\Box$ 

We now turn to decidability of questions related to RA-plans for TGDs with terminating chase. Unlike AcSch, the bidirectional schema AcSch<sup>\(\theta\)</sup> does not preserve the terminating chase property. However, one can check that for many well-known classes with terminating chase, such as weakly acyclic TGDs, the schema AcSch<sup>\(\theta\)</sup> is also in the same class. Hence, the analog of Theorem 5.7 holds for such classes as well.

### 6. LOW-COST PLANS VIA PROOF SEARCH

We have seen that proofs of an entailment can lead us to *some* successful plan whenever one exists.

We now look at finding efficient plans, focusing for the remainder of the article on generating *SPJ*-plans with respect to schemas consisting of TGDs.

*Example* 6.1. We return to the variant of Example 1.3 mentioned in the introduction. We have a Profinfo(eid, onum, lname) data source with one access method  $\mathsf{mt}_{\mathsf{Profinfo}}$  requiring an eid as an input. There are also tables  $\mathsf{Udirectory}_1(\mathsf{eid}, \mathsf{lname})$  with input-free access method  $\mathsf{mt}_1$  and  $\mathsf{Udirectory}_2(\mathsf{eid}, \mathsf{lname})$  with input-free access method  $\mathsf{mt}_2$ . The constraints include two inclusion dependencies:

 $\forall$ eid  $\forall$ onum  $\forall$ Iname Profinfo(eid, onum, Iname)  $\rightarrow$  Udirectory, (eid, Iname)

for i=1,2. Our goal is to generate an SPJ-plan for query  $Q=\mathsf{Profinfo}(\mathsf{eid},\mathsf{onum},$  "Smith").

The corresponding auxiliary schema will add tables  $InfAccUdirectory_1$ ,  $InfAccUdirectory_2$ , and InfAccProfinfo. The axioms will be the Sch constraints, InfAccCopy constraints, and "accessibility axioms" that include the following axioms, labeled  $(UA_i)$ , for i=1,2:

 $\forall$ eid  $\forall$ Iname Udirectory<sub>i</sub>(eid, Iname)  $\rightarrow$ 

 $InfAccUdirectory_i(eid, onum, Iname) \land accessible(eid) \land accessible(Iname).$ 

Also included will be the accessibility axiom (*PA*):

 $\forall eid \, \forall onum \, \forall Iname \, accessible(eid) \, \land \, Profinfo(eid, \, onum, \, Iname) \rightarrow \\ InfAccProfinfo(eid, \, onum, \, Iname) \, \land \, accessible(onum) \, \land \, accessible(Iname)$ 

and the ground accessibility axiom:

accessible("Smith").

A chase proof will begin with the canonical database of *Q*, namely:

Profinfo(eid<sub>0</sub>, onum<sub>0</sub>, "Smith").

Our general strategy will be that before looking for accessibility axioms to fire, we look first for any nonaccessibility axioms we can apply first. Thus, we apply the two original inclusion dependencies to add facts:

Udirectory<sub>2</sub>(eid<sub>0</sub>, onum<sub>0</sub>, Iname<sub>0</sub>), Udirectory<sub>2</sub>(eid<sub>0</sub>, onum<sub>0</sub>, Iname<sub>0</sub>).

22:32 M. Benedikt et al.

We also fire the axiom generating fact accessible ("Smith"), representing the fact that "Smith" is a known constant. If we model this accessibility axiom as corresponding to a special kind of "access method," it would clearly be a method with no cost.

Continuing from this are several possible proofs. One proof will apply a chase step with the rule  $(UA_1)$  to add facts

InfAccUdirectory<sub>1</sub>(eid<sub>0</sub>, onum<sub>0</sub>, "Smith"), accessible(eid<sub>0</sub>)accessible(onum<sub>0</sub>),

followed by a chase step with (PA) to add fact

InfAccProfinfo(eid<sub>0</sub>, onum<sub>0</sub>, "Smith").

At this point, we have a match for InfAcc *Q*, and hence a complete chase proof.

Instantiating the TGD-based plan generation algorithm (as in Figure 1, modified as

Instantiating the TGD-based plan generation algorithm (as in Figure 1, modified as in Section 5.1 to account for constants), we will generate the plan:

```
\begin{split} T_1 &\leftarrow \mathsf{mt}_1 \leftarrow \emptyset \\ T_2 &:= \sigma_{\mathsf{Iname="Smith}}"T_1 \\ T_3 &\leftarrow \mathsf{mt}_{\mathsf{Profinfo}} \leftarrow \pi_{\mathsf{eid}}(T_2) \\ \mathsf{Return} \ \pi_{\mathsf{onum}}(T_3) \end{split}
```

A second proof would be similar, but using  $(UA_2)$  rather than  $(UA_1)$ . This would generate a plan that corresponded to an access to Udirect<sub>2</sub> rather than Udirect<sub>1</sub>.

A third proof would first fire  $(UA_1)$  and then  $(UA_2)$ , followed by (PA). Applying the TGD-based algorithm would automatically generate the plan:

```
\begin{split} T_1 &\leftarrow \mathsf{mt}_1 \leftarrow \emptyset \\ T_2 &:= \sigma_{\mathsf{Iname="Smith"}} T_1 \\ T_3 &\leftarrow \mathsf{mt}_2 \leftarrow \emptyset \\ T_4 &:= \sigma_{\mathsf{Iname="Smith"}} T_3 \\ T_5 &:= T_2 \bowtie T_4 \\ T_6 &\leftarrow \mathsf{mt}_{\mathsf{Profinfo}} \leftarrow \pi_{\mathsf{eid}}(T_5) \\ \mathsf{Return} \ \pi_{\mathsf{Onum}}(T_5) \end{split}
```

What we see is that each "interesting plan" is captured by a distinct proof. Which of these plans has the lowest cost will depend on, for example, the relative efficiency of the access methods  $\mathsf{mt}_1$  and  $\mathsf{mt}_2$ , along with the amount of tuples each returns. Thus, we cannot make a decision on which plan is most efficient simply by looking at the proof. What we can do is explore this space of proofs while measuring the efficiency of the corresponding plans.

**How good are proof-based plans?** We now consider our first question about cost. Are proof-based plans as "cheap" as general plans?

We first consider a cost comparison between plans and conjunctive queries.

Recall from Section 3 that a conjunctive query Q with atoms  $A_1 \ldots A_n$  is executable relative to a schema with access patterns [Li and Chang 2000] if there is an annotation of each atom  $A_i = R_i(\vec{x_i})$  with an access method  $\mathsf{mt}_i$  on R such that for each variable x of Q, for the first  $A_i$  containing x, x occurs only in an output position of  $\mathsf{mt}_i$ . Proposition 3.1 provides a function PlanOf that converts every executable  $\mathsf{CQ}\ Q$  to an SPJ-plan PlanOf(Q) such that the number of accesses in the plan equals the number of atoms in the query, and conversely a function taking a plan PL to an executable query  $\mathsf{CQOf}(\mathsf{PL})$  where the number of atoms in the query equals the number of accesses in the plan.

The following proposition shows that proof-based plans perform as well as executable CQs, for any notion of cost that is based on the set of methods called.

PROPOSITION 6.2. For every CQ Q, schema Sch, and executable query Q' equivalent to Q, there is a proof v such that if  $PL^v$  is the SPJ-plan produced by the proof-to-plan

algorithm, then  $CQOf(PL^v)$  has at most the number of atoms as Q', and  $PL^v$  uses no more methods than PlanOf(Q').

In particular, the cost of  $PL^{v}$  will be no more than that of PlanOf(Q') under any simple cost function.

PROOF. Let Q' be an executable query as earlier, with atoms  $A_1 \ldots A_n$ ,  $A_i = R_i(\vec{x_i})$ , and let  $Q'_i$  be the subquery conjoining atoms  $A_1 \ldots A_i$ . Let  $\operatorname{config}_{\infty}$  be a (possibly infinite) instance resulting from chasing the canonical database of Q with the constraints of Sch. Q has a match on the elements in  $\operatorname{config}_{\infty}$  corresponding to free variables of Q, and since Q' is equivalent to Q on instances satisfying the constraints, Q' must have such a match on  $\operatorname{config}_{\infty}$  as well.

There is thus a finite subinstance  $\operatorname{config}_0$  of  $\operatorname{config}_\infty$  on which Q' returns the elements corresponding to the free variables of Q. Although Q' consisted of n atoms, when evaluating  $\operatorname{PlanOf}(Q')$  on  $\operatorname{config}_0$  we may have exposed many more than n facts. We can choose a single tuple  $F_i$  matching atom  $A_i$  so that there is a match of Q' on  $F_1 \dots F_n$ .

We begin our chase proof by building  $\operatorname{config_0}$  and then firing the accessibility axioms that correspond to expose each  $F_i$ . Using the fact that Q' was executable, we can see that after exposing  $F_1 \dots F_{i-1}$ , all values occurring in  $F_i$  within input positions of method  $\operatorname{mt}_i$  will satisfy accessible. Note that the facts  $F_1 \dots F_n$  may not be distinct, in which case it will be unnecessary to fire n accessibility axioms to expose  $F_1 \dots F_n$ .

We now argue that we can complete the chase sequence into a proof by firing InfAccCopy rules. Consider the instance consisting of facts  $F_1 \dots F_n$ , with each relation R renamed to InfAccR, and let  $\operatorname{config'_{\infty}}$  result from chasing this instance with the InfAccCopy rules.  $\operatorname{config'_{\infty}}$  clearly satisfies all the InfAccCopy constraints. Since  $F_1 \dots F_n$  led to a match for Q, the query InfAccQ has a match on  $\operatorname{config'_{\infty}}$ . As Q and Q are equivalent on instances satisfying the Sch constraints, InfAccQ and InfAccQ are equivalent on instances satisfying the copy of the constraints. Therefore, there is a finite subinstance  $\operatorname{config'_{0}}$  of  $\operatorname{config'_{\infty}}$  containing a match for InfAccQ. We complete our chase proof by firing InfAccCopy rules to generate  $\operatorname{config'_{0}}$ . Because the resulting chase sequence v consists of firing Sch constraints, accessibility axioms, and InfAccCopy constraints, beginning with the canonical database of Q and leading to a configuration with a match for InfAccQ, it represents a chase proof of our entailment. Therefore, the corresponding plan  $\operatorname{PL}^v$  is equivalent to Q. The access commands in  $\operatorname{PL}^v$  correspond to the accessibility axioms needed to expose  $F_1 \dots F_n$ , which will in turn be a subsequence of the method sequence used in  $\operatorname{PlanOf}(Q')$ .  $\square$ 

A similar argument shows that for any plan that has a "left-deep" structure, joining on one access at a time, there is a proof-based plan that uses no more methods than it.

Example 6.3. The following example shows a case where proof-based plans are not as efficient as general plans.

Consider the query

$$Q = \exists xyz \, S(x) \land S(y) \land R(x, w) \land R(y, z) \land U(w) \land V(z)$$

and a schema where

- —there is an input-free access  $\mathsf{mt}_S$  on S,
- —there is an access method  $\mathsf{mt}_R$  accessing R on the first position, and
- —there are access methods  $\mathsf{mt}_U$  and  $\mathsf{mt}_V$  requiring the sole position on U and V, respectively.

22:34 M. Benedikt et al.

This is an executable CQ with six atoms. However, one can obtain the following plan PL to answer Q, which uses only four access commands:

```
\begin{split} U_1(x) & \Leftarrow \mathsf{mt}_S \Leftarrow \emptyset \\ U_2(y) &:= \mathsf{rename}\ U_1 \\ U_3(x,w) & \Leftarrow \mathsf{mt}_R \Leftarrow U_2 \\ U_4(y,z) &:= \mathsf{rename}\ U_3 \\ U_5(w) & \Leftarrow \mathsf{mt}_U \Leftarrow \pi_w(U_3) \\ U_6(z) & \Leftarrow \mathsf{mt}_V \Leftarrow \pi_z(U_4) \end{split} Return U_1 \bowtie U_2 \bowtie U_3 \bowtie U_4 \bowtie U_5 \bowtie U_6
```

Here the renaming operations are syntactic sugar to make the variables clearer. The plan first accesses S to get possible values of x and y, then uses the resulting values in R. The output is then put in U and in V, and then the results are stitched together using a join. The plan answers Q.

Note that this plan does not have the "left-deep" shape produced by either proofbased plans or the naïve translation of executable queries. And indeed, there is no proof-based plan that generates a plan with this number of access commands.

Let the initial configuration of the chase contain

$$\{S(x_0), S(y_0), R(x_0, w_0), R(y_0, z_0), U(w_0), V(z_0)\}.$$

A chase-based proof along these lines would proceed via the following rule firings:

```
\begin{array}{l} -S(x_0) \rightarrow \mathsf{InfAcc}S(x_0) \\ -S(y_0) \rightarrow \mathsf{InfAcc}S(y_0) \text{ as well as generating accessible}(x_0), \, \mathsf{accessible}(y_0) \\ -R(x_0, w_0) \wedge \mathsf{accessible}(x_0) \rightarrow \mathsf{InfAcc}R(x_0, w_0) \\ -R(y_0, z_0) \wedge \mathsf{accessible}(x_0) \rightarrow \mathsf{InfAcc}R(y_0, z_0) \\ -U(w_0) \wedge \mathsf{accessible}(w_0) \rightarrow \mathsf{InfAcc}U(w_0) \\ -V(z_0) \wedge \mathsf{accessible}(z_0) \rightarrow \mathsf{InfAcc}V(z_0) \end{array}
```

These rules generate inferred accessible facts that match InfAccQ. Note that there are two rule firings on relation R.

If we put the previous proof sequence into our plan generation algorithm, we get a plan that will have six access commands, one for each firing. The plan PL' will still generate two calls to access method R, unlike the previous one. These calls will use the same inputs, and in an intelligent wrapper that caches the results of prior accesses made, the second call will require no tuples. Related observations about the superiority of "bushy plans" to left-deep plans in the presence of access restrictions have been known for some time: see, for example, Florescu et al. [1999], Example 3.2.

One can see that the two plans generate exactly the same concrete accesses. But the number of "bulk method calls" is larger in PL'; hence, a cost function that counts the number of calls will give a higher cost to PL' than to PL.

We now compare proof-based plans and general (not necessarily left-deep) plans in terms of the set of accesses made at runtime. An SPJ-plan PL uses no more runtime accesses than SPJ-plan PL', denoted PL  $\leq_{\mathsf{RTA}}$  PL', if for every pair consisting of a method mt and method input  $\vec{t}$  that is executed in running PL on instance I of the schema, the same pair is also executed in running PL' on I.

We show that proof-based plans are optimal with respect to arbitrary plans when runtime accesses are considered:

Theorem 6.4. For conjunctive query Q and access schema with TGD constraints  $\Sigma$ , for every SPJ-plan PL that answers Q, there is a chase sequence v proving InfAccQ, such

that, letting  $PL^v$  be the SPJ-plan  $PL^v$  generated from v via the proof-to-plan algorithm,  $PL^v \preceq_{RTA} PL$ .

Note that this theorem does not imply anything about the cost of proof-based plans versus arbitrary plans according to particular cost functions, since cost functions look at plans statically, and are thus not necessarily monotone in the set of (method, input) pairs produced at runtime.

The proof of this result is deferred to an Online Appendix available via the ACM Digital Library.

Summarizing, if we are interested only in the number of accesses generated at runtime, it suffices to look at proof-based plans. In addition, if we measure cost via some function of the set of access commands (ignoring middleware cost), then proof-based plans are as good as arbitrary "left-deep" plans. Although most realistic cost functions would consider more than just the set of commands, we take this as a rough justification for restricting to proof-based plans.

### 6.1. Simultaneous Proof and Plan Search

We now turn to algorithms that search for a low-cost proof-based plan.

Note that in the algorithm that generated *SPJ*-plans from proofs, the plans were generated inductively on the number of steps in a prefix of a proof. Consequently, we can associate a partial plan to a partial proof. This allows us to measure the cost of the corresponding partial plan during proof exploration. These two observations underlie the idea that we can find low-cost plans by exploring the space of proofs.

Our search will maintain a partial proof tree—a tree consisting of chase sequences, ordered by extension. We refer to the configuration of the final element in the chase sequence associated with a node v as  $\mathsf{config}(v)$ . The plan associated with v is the one generated by the proof-to-plan algorithm given previously, while by the cost of v we mean the cost of the associated plan. We now give an algorithm for extending the tree to find new proofs.

Definition 6.5 (Candidate Facts for Exposure). Consider a node v such that there is a fact  $R(c_1 \ldots c_m)$  in  $\operatorname{config}(v)$  with  $\operatorname{InfAcc} R(c_1 \ldots c_m)$  not yet in  $\operatorname{config}(v)$  and there is an access method mt on R with input positions  $j_1 \ldots j_m$  such that  $\operatorname{accessible}(c_{j_1}) \ldots \operatorname{accessible}(c_{j_m})$  all hold in  $\operatorname{config}(v)$ . Then we call  $R(c_1 \ldots c_m)$  a candidate for exposure at v, and mt an exposing method for  $R(c_1 \ldots c_m)$ .

Note that if a fact is a candidate for exposure, then firing an accessibility axiom will add that fact to the associated chase sequence.

When we explore the impact of making an access, we want to include all relevant consequences that do not involve further accesses, thus producing an *eager proof*, which corresponds to the following requirements on the configurations in a partial proof tree:

- —(Original Schema Reasoning First) The configuration of the root node (henceforward "initial configuration") corresponds to the canonical instance of Q plus the result of firing of a sufficient sequence of Sch integrity constraints until a termination condition is reached—the notion of sufficient sequence will be explained further later.
- —(Fire Inferred Accessible Rules Immediately) For a nonroot node v, there is a candidate fact for exposure  $R(c_1 \dots c_m)$  in its parent with exposing method mt such that  $\mathsf{config}(v)$  is obtained from the parent by
  - —adding the fact induced by firing mt with  $c_{j_1} \dots c_{j_m}$ , namely, InfAcc $R(d_1 \dots d_m)$ , or
  - —firing a sufficient set of inferred accessible axioms on the result.

22:36 M. Benedikt et al.

## ALGORITHM 2: Plan Search

14 return BestPlan;

```
Input: query Q, schema S
   Output: plan BestPlan
1 ProofTree := an initial node v_0 labeled with the configuration obtained by a sufficient
   number of firings of Sch constraints.
2 Set Candidates(v_0) = all pairs (R(c_1 \dots c_n), mt) with R(c_1 \dots c_n) a fact in the original
   configuration and mt a method on R.
3 BestPlan := \bot
4 BestCost := \infty
5 while there is a nonterminal node v \in ProofTree do
       Choose such a node v.
6
       Choose a candidate fact and method (R(c_1 \dots c_n), \mathsf{mt}) \in \mathsf{Candidates}(v) with
7
       accessible(c_{j_1}) \dots accessible(c_{j_m}) \in config(v) and mt having inputs j_1 \dots j_m.
       Add a new node v' as a child of v with configuration formed by adding InfAccR(c_1 \dots c_n)
8
       a sufficiently large closure by firings of the InfAccCopy constraints.
       Remove (R(c_1 \dots c_n), mt) from Candidates(v), marking v as terminal if it has no more
9
       candidates.
       Determine if v' is successful by checking if InfAcc Q holds, and if so also mark it as
10
       terminal.
       if v' is successful and Cost(Plan(v')) < BestCost then
11
           BestPlan := Plan(v')
12
           BestCost := Cost(Plan(v'))
13
```

Thus, the successive configurations are connected by firing a rule associated with an accessibility axiom and exploring the "cost-free" consequences. Thus, we can also characterize a node v by the sequence of rule firings of accessibility axioms leading to it. It is easy to see that an arbitrary proof can be converted into an eager proof via re-ordering.

We also label a node as successful if InfAccQ holds in the corresponding configuration (preserving free variables in the non-Boolean case).

The idea is that we have labeled each node with a configuration of the proof, and whenever we choose an accessibility axiom to fire, after firing we immediately fire all the relevant rules that do not generate accesses.

We explore downward from a node v of a partial proof tree by choosing a *candidate* fact for exposure at config(v) along with the methods that expose the fact. A node is terminal if it is either successful or has no candidate facts. Note that nonterminal nodes do not have to be leaves of the tree. We continue until a sufficient set of accessibility axioms have been fired.

The basic search structure is outlined in Algorithm 2. At each iteration of the while loop at line 5, we have a partial proof/plan tree satisfying the properties earlier. We look for a node v corresponding to a partial proof that is not yet successful, and for which the firings of accessibility axioms can add new facts. We nondeterministically choose such a path and such an axiom (lines 6–7) and calculate the new configuration that comes from firing the rule, along with the commands that will be added to the corresponding plan (line 8). We update the candidate list (line 9) and determine whether the new path is successful, recording whether this gives the new lowest cost plan (line 11).

**Termination.** In Algorithm 2, there are several points where we limit the search to achieve termination. Formally, we need the following: (1) A finite sequence  $v_0$  formed by closing the canonical query Q under firings of Sch rules. We use this set in the step of chasing with the Sch constraints in line 1. Given  $v_0$ , we have a bound on termination of

the while loop of line 5, since we only expose facts from  $v_0$ . (2) For each chase sequence  $w_0$ , an extension  $v'(w_0)$  of  $w_0$  by firing InfAccCopy constraints, used within every step of the while loop on line 8.

For classes with terminating chase, we set  $v_0$  to be any set of firings of Sch rules such that there are no active triggers of Sch constraints. We let v'(w) be any extension of w by InfAccCopy constraints with no active triggers among InfAccCopy constraints.

We can show that this algorithm will solve the low-cost plan problem for proof-based plans.

Theorem 6.6. Consider any simple cost function Cost, access schema Sch whose constraints are TGDs with terminating chase, and conjunctive query Q. Then Algorithm 2, instantiated with the sufficient sets earlier and the cost function Cost, will always return a plan with the lowest cost among all those proof-based plans that completely answer Q w.r.t. Sch, or return  $\bot$  if there is no plan that answers Q.

Proof. Consider any chase proof w that Q entails InfAccQ. Such a w can be extended so that there are no active triggers among Sch or InfAccCopy constraints, without changing the resulting plan. Let  $PL^w$  be the plan and  $mt_1 \dots mt_n$  the sequence of access methods within the access commands of  $PL^{w}$ . Let  $v_0$  be the chase sequence described by chasing the canonical database with Sch rules, as described earlier, and  $\mathsf{config}_0$ be the final chase configuration in  $v_0$ . When  $PL^w$  is run on config<sub>0</sub>, it will execute access commands Command'<sub>1</sub>...Command'<sub>n</sub> with inputs  $I_1...I_n$ , with the output of the access being  $O_1...O_n$ . As in the proof of Proposition 6.2, we can find facts  $F_1...F_n$  with corresponding tuples  $\vec{t}_1 \in O_1...\vec{t}_n \in O_n$  accessed by  $\mathsf{PL}^w$  on  $\mathsf{config}_0$  such that these outputs suffice to return the tuple corresponding to the free variables of Q. Let v' be the chase sequence corresponding to firings of accessibility axioms exposing  $F_1 \dots F_n$ on config<sub>0</sub>. Arguing as in the proof of Proposition 6.2, we can see that this represents a valid sequence of firings, since the values of  $t_i$  lying within the input positions of  $\mathsf{mt}_i$  will satisfy accessible. Arguing as in Proposition 6.2 again, we see that  $v_0 \cdot v'$ can be extended by the firing of some collection of InfAccCopy constraints  $v_3$ , giving a proof of the entailment of InfAccQ from Q. Letting  $v = v_0 \cdot v' \cdot v_3$ , we claim that the corresponding plan PL<sup>v</sup> will be discovered by the algorithm. Since PL<sup>v</sup> uses no more methods than PL<sup>w</sup> and our cost function is simple, the cost of PL<sup>v</sup> will be no higher than that of  $PL^{w}$ . Thus, if  $PL^{v}$  is discovered by the algorithm, we have proven optimality.

Consider the chase sequence  $v^*$  formed from  $v_0 \cdot v' \cdot v_3$  by removing  $v_3$  and inserting after each prefix  $p_3$  of  $v_0 \cdot v'$  a chase sequence of InfAccCopy constraints that are applicable after that prefix, until there are no InfAccCopy constraints that can apply.  $\mathsf{PL}^{v^*}$  and  $\mathsf{PL}^v$  are the same, since the accessibility axiom firings in both sequences are identical. We can also see that  $v^*$  will have a match for InfAccQ. This holds because both  $v^*$  and v extend the sequence  $v_0 \cdot v'$  by firing InfAccCopy constraints until there are no active triggers by InfAccCopy constraints, and hence, they both satisfy exactly the CQs that are implied by the final configuration of  $v_0 \cdot v'$  and the InfAccCopy constraints.

We argue that in every iteration of the while loop, (i) if  $v^*$  has not been discovered, then the while loop at line 5 will not yet terminate, and  $v^*$  will always have a prefix in ProofTree with a nonempty set of candidates. Since candidates are removed in each iteration of the while loop, eventually such an ancestor prefix will be chosen to be expanded, and thus  $v^*$  will be discovered.  $\Box$ 

Such sufficient sets also exist for classes without terminating chase, such as GTGDs. Instead of firing the rules until termination, it is enough to fire them a sufficient number of times. The details of this result are given in the Online Appendix.

22:38 M. Benedikt et al.

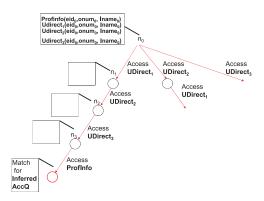

Fig. 2. Exploration in the running example.

*Example* 6.7. Let us return to the setting of Example 1.3, assuming we have three directory sources Udirect<sub>1</sub>, Udirect<sub>2</sub>, Udirect<sub>3</sub>. The integrity constraints contain

Profinfo(eid, onum, Iname)  $\rightarrow$  Udirect<sub>i</sub>(eid, Iname)

for i=1,2,3, with Profinfo having an access that requires the first argument to be given and each Udirectory<sub>i</sub> having unrestricted access. Consider the query  $Q=\exists \text{eid} \text{ onum | name Profinfo(eid, onum, lname)}.$ 

The behavior of our exploration is illustrated in Figure 2. The canonical database of Q consists of the fact Profinfo(eid<sub>0</sub>, onum<sub>0</sub>, lname<sub>0</sub>). The configuration of the initial node  $n_0$  will then add Udirect<sub>i</sub>(eid<sub>0</sub>, lname<sub>0</sub>) for i = 1, 2, 3. There are thus three candidate facts to expose, Udirect<sub>i</sub>(eid<sub>0</sub>, lname<sub>0</sub>): i = 1, 2, 3, in the initial node.

We might choose  $\mathsf{Udirect}_1(\mathsf{eid}_0, \mathsf{Iname}_0)$  to expose first. This creates a child  $n_1$  with transition from parent to child associated with an access on  $\mathsf{Udirect}_1$ , putting the output into a table  $T_1$  with attributes  $\{\mathsf{eid}_0, \mathsf{Iname}_0\}$ . The configuration for  $n_1$  adds the fact  $\mathsf{InfAccUdirect}_1(\mathsf{eid}_0, \mathsf{Iname}_0)$ , and then immediately the fact  $\mathsf{InfAccUdirect}_1(\mathsf{eid}_0, \mathsf{Iname}_0)$ , accessible( $\mathsf{eid}_0$ ), and accessible( $\mathsf{Iname}_0$ ).

In  $n_1$ , there are three candidates to expose:  $Udirect_2(eid_0, Iname_0)$ ,  $Udirect_3(eid_0, Iname_0)$  and now also  $Profinfo(eid_0, onum_0, Iname_0)$ , since there is an accessibility axiom that would expose this last fact now. Again, based on some ordering policy, we might choose  $Udirect_2(eid_0, Iname_0)$  to expose, and a child  $n_2$  will be generated (again including the exposed fact  $InfAccUdirect_2(eid_0, Iname_0)$  and one inferred fact). The transition to  $n_2$  will be associated with an access command on  $Udirect_2$  and a command joining the results with the previous table.

The node  $n_2$  will have two candidates to expose,  $Udirect_3(eid_0, Iname_0)$  and  $Profinfo(eid_0, onum_0, Iname_0)$ . Assuming our policy chooses to expose  $Udirect_3(eid_0, Iname_0)$  next, we will generate a child  $n_3$ , whose configuration adds the exposed fact and the corresponding inferred accessible fact.

The node  $n_3$  will have only one candidate fact, corresponding to Profinfo(eid<sub>0</sub>, onum<sub>0</sub>, lname<sub>0</sub>). Selecting this fact, a child  $n_4$  will be generated. The access associated with the addition of  $n_4$  will be of the form  $T_4 \Leftarrow \mathsf{mt}_{\mathsf{Profinfo}} \Leftarrow T_3$ , where  $T_3$  will be a table with attributes eid<sub>0</sub>, lname<sub>0</sub> containing the intersection of the outputs of the three prior accesses. The query  $\mathsf{Inf}\mathsf{Acc}Q$  matches the configuration of  $n_4$ , so it is designated a success node, and hence is a leaf in the search.

Now the search can go back up the tree to a node with more candidates to explore—for example, it might move to pick a child of  $n_3$  to explore.

Note that at some point in the process, the extension process will consider creating a node n''' corresponding to the sequence of commands  $T_1 \leftarrow \mathsf{mt}_{\mathsf{Udirect}_2} \leftarrow \emptyset$ ;  $T_2 \leftarrow \mathsf{mt}_{\mathsf{Udirect}_1} \leftarrow \emptyset$ , and continuing on this way will explore all left-deep join trees between the  $\mathsf{Udirect}_i$  data sources.

#### 7. CONCLUSIONS AND FUTURE WORK

The main goal of this work is to introduce a means for generating query plans from proofs that a certain semantic property holds for the query. We show that the proof goals can be modified for different kinds of target plans. We give some evidence that the plans that are generated by proofs are as good as general plans under some metrics, and show that by exploring many proofs, one can arrive at optimal proof-based plans.

In follow-on work, we discuss implementation of a system based on generating plans from proofs [Benedikt et al. 2014, 2015]. In current work, we are extending the system to more general constraints beyond TGDs, using a tableau-based proof system.

### 8. RELATED WORK

Work on querying in the presence of access patterns without integrity constraints. Work on access patterns was initially motivated by the goal of finding indexonly plans over a fixed set of indices in traditional databases [Ullman 1989; Rajaraman et al. 1995]. Li and Chang [2001] and Li [2003] later explored the complexity of determining when a query could be answered in the presence of access patterns, where answering the query referred to coming up with an executable query. Extensions to richer queries were considered by Nash and Ludäscher [2004a, 2004b]. Florescu et al. [1999] look at integrating access restrictions into a cost-based optimizer.

In the absence of integrity constraints, querying with access patterns amounts to a limitation on the search space, restricting the ordering of atoms within a query plan. In contrast, schemas with integrity constraints and access patterns can simultaneously restrict the search space (via access restrictions) and extend it (via integrity constraints, which allow relations outside of the query to become relevant).

Comparison to work of Nash, Segoufin, and Vianu. The departure point for this article is the work of Segoufin and Vianu [2005] and Nash et al. [2010], which introduce the idea of relating a semantic property of a query relative to an interface restriction—in their case, determinacy of a query by views—with the existence of a reformulation of the query over the views.

This idea is not phrased in terms of algorithms going from proofs of the semantic property to reformulations, since Nash et al. [2010] do not work by default in the setting of unrestricted instances (as we do), but in the setting of finite instances, and over finite instances semantic entailment is not necessarily the same as the existence of a proof. Indeed, Nash et al. [2010] investigate the question of determinacy versus reformulation in the finite in detail.

Nash et al. [2010] discovered that even in the setting of conjunctive query views, conjunctive queries may have a relational algebra reformulation but no conjunctive query reformulation. They defined the corresponding semantic property for positive existential reformulation, the analog of our access monotonic determinacy definition in the view case. However, there is no investigation of the different notions of determinacy that correspond to different kinds of target queries in Nash et al. [2010].

We give theorems not for reformulation as a query but for plan generation using access methods. We emphasize the semantic property and proof goal that correspond to each notion of plan, stressing that one can go effectively from the proof to the plan. Although this correspondence relies on considering equivalence over all instances, we show that it can be "pushed down" to equivalence over finite instances for many classes of constraints considered in practice (e.g., those with terminating chase).

22:40 M. Benedikt et al.

In short, our work can be seen as generalizations of Nash et al. [2010] to the setting with access patterns and constraints, stressing the relationship between semantic properties, proofs, and plans.

Our algorithm for generating RA-plans is extremely close to the construction in the case of reformulation over conjunctive query view definitions on page 21:29 of Nash et al. [2010]. The construction of Nash et al. [2010] is quite specific to the conjunctive query view case.

Comparison with the Chase and Backchase. The Chase and Backchase (C&B) is a common technique for reformulating a conjunctive query Q. It originated in papers of Popa [2000], Tannen, and Deutsch (e.g., Deutsch et al. [1999, 2006]). The technique exists in various forms, but a frequently cited version of it matches our SPJ-plan algorithm in the special case of "vocabulary-based access restrictions": we have a distinguished set of predicates  $\mathcal{T}$  that the reformulated query should be over, and we desire a conjunctive query reformulation  $Q_T$ . In terms of constraints, there are versions of the C&B for constraint sets including both tuple-generating dependencies and equality-generating dependencies (EGDs). The main assumption is that we have a notion of the chase that terminates. Such a variant is well known for TGDs and EGDs, but the requirements for termination of the chase become very strong [Onet 2013]. Next we will explain the connection between the C&B and the results in this article only for TGDs.

The idea of the C&B is to first produce a "universal plan" by chasing the canonical instance of query Q with the constraints to get a collection of facts U: this is the "chasing phase." Then we search for a smaller plan that uses only the distinguished predicates from  $\mathcal{T}$ . We do this by selecting a set S of such facts within the chase, rechasing it by tracing out the closure of S in U under the dependencies. If this closure has a match of the query Q (i.e., a homomorphism mapping the free variables of Q to the corresponding constant), then we know that the set of atoms S, when converted to a query  $Q_S$ , is in fact equivalent to Q under the constraints. This is the "back-chasing" phase. Ideally, it will select a set S that is minimal with respect to having a chase closure with a match for Q, thus producing a  $Q_S$  that is a minimal reformulation [Ileana et al. 2014]. By maintaining auxiliary information about the way in which the atoms in U are generated in the chase, the back-chasing phase can be made more efficient. For example, in Ileana et al. [2014], provenance information is maintained to speed up the back-chasing phase.

We have looked not at generating a query, but at plan generation in the presence of access restrictions and constraints, and the technique given here—auxiliary schemas, two copies of the relation symbols, and so forth—may seem very distinct from the C&B. But we will explain here that in the case where the methods overlap—that is, where one is interested in generating an SPJ query over a subset of the relations, for constraints having a terminating chase—our approach is a variation of the C&B.

Recall that in Algorithm 2, we first form an initial chase using the Sch constraints  $\Sigma$ , and then apply steps consisting of firing an accessibility axiom followed by "follow-up rules"—the application of copies of the constraints. Instead of firing an accessibility axiom to explicitly generate a fact of the form  $InfAccR(\vec{c})$ , we could simply decorate the fact  $R(\vec{c})$  by a special predicate B (for "back-chased") and then propagate predicate B through the initial chase. Thus, choosing a path of accessibility axioms corresponds exactly to choosing a sequence of distinct atoms  $s_1 \dots s_n$ . The result of our plan generation algorithm is a physical plan implementing the conjunctive query corresponding to the underlying set of atoms  $\{s_1 \dots s_n\}$ . If we take as a cost metric the number of access commands, then our cost-based method will automatically minimize this among proofbased plans. Proposition 6.2 argues that the resulting plan will minimize the number

of atoms in the corresponding query. Thus, in particular, this will allow us to produce a minimal reformulation.

In summary, from a high level, the C&B method corresponds to our approach as follows: the chasing phase corresponds to applying the Sch constraints, a choice of atoms corresponds to firing accessibility atoms, while the back-chasing phase can be seen as applying the InfAccCopy constraints.

There are some distinctions between Algorithm 2 and the C&B:

- —Algorithm 2 explores different chase *sequences*, while the C&B takes an unordered view of the chase, producing a set of atoms that are turned into a query. For binding pattern-based access restrictions, the ordering of the chase corresponds to the ordering of accesses, which is critical to making the plan executable. For "vocabulary-based restrictions," where a subset of the relations is made accessible (as in the setting of views), Algorithm 2 can explore plans corresponding to different join orders, as discussed in Example 6.7.
- —Algorithm 2 is cost based. While the classic C&B algorithm deals only with getting minimal reformulations, this is not a fundamental limitation of the C&B approach, and cost-based extensions are considered in Popa's thesis [Popa 2000].
- —By considering the back-chasing phase as a retracing of the original chase graph, the C&B can speed up the process of checking equivalence of S. This viewpoint is critical to the optimizations performed in C&B papers, such as Meier's [Meier 2014] and Ileana et al.'s [Ileana et al. 2014]. This optimization is usually presented in the setting of terminating chase, although it could be modified in the same way as we do to the setting of broader classes (e.g., GTGDs), creating the chase up to a point sufficiently large that a proof will be found if there is one. Although C&B usually couples a "proof-to-reformulation" algorithm with a particular algorithmic strategy of forming the full universal chase first, these two could also be decoupled, as our algorithms are presented here. For instance, one could interleave chasing the canonical database and "back-chasing" (choosing some atoms and seeing their consequences), and this might have advantages when the full chase is large or infinite.

The usual presentation of the C&B, as well as Algorithm 2, is focused on CQ reformulations/SPJ-plans. The C&B has been extended to deal with unions of conjunctive queries with atomic negation (see the discussion of Deutsch et al. [2007] in this section), but not to relational algebra reformulation. In this work, we have considered existential plan generation but have shown that it collapses to the SPJ-plan generation when inputs are constraints are TGDs. We have also considered relational algebra plan generation.

In considering the entailments and semantic properties corresponding to different kinds of plans, we have underscored the connection between semantic properties like determinacy, proofs of their entailments, and plan generation. This connection is the main contribution of our article. The conference paper [Benedikt et al. 2014] extends this approach presented here to first-order constraints, while the later work [Benedikt et al. 2015] discusses implementation and experiments. We defer a comparison of the C&B with these later developments to another work.

**Comparison with Deutsch et al. [2007].** The first paper on querying with integrity constraints and access patterns is Deutsch et al. [2007].

Deutsch et al. [2007] do not define a plan language, but rather deal with getting an "executable UCQ": a UCQ query that can be executed using the access patterns in the obvious way. We have shown in the Online Appendix that these correspond to our notion of the USPJ-plan in expressiveness. Our Theorem 4.6 shows that if one starts with a CQ and the constraints consist only of TGDs, negation and union are

22:42 M. Benedikt et al.

not necessary to answer the query. But Deutsch et al. [2007] allow the source query Q to be a  $USPJ^-$  query, and allow constraints with disjunction and atomic negation on both sides. Thus, our result does not apply to their setting. Although the constraints and source queries considered in Deutsch et al. [2007] are richer than those dealt with here, the algorithms are specific to the case where the chase terminates.

Deutsch et al. [2007] deal with the *existence problem* of determining whether a query has an equivalent  $USPJ^-$  executable query, as well as the problem of finding such a query if it exists.

In Section 4 of the paper, they define an algorithm for the existence problem:

- (1) Apply the chase procedure to the original query Q with the constraints until termination. Deutsch et al. [2007] chase the queries directly to get another query, rather than dealing with the corresponding canonical database to get an instance. Thus, for them, the result of the chase is another query  $Q_1$ .
- (2) Form a query  $Q_2$  as the "answerable part" of  $Q_1$ : this is (informally) a maximal subquery of  $Q_1$  that can be generated using the access patterns.
- (3) Chase  $Q_2$  to get a new query  $Q_3$ , and check whether  $Q_3$  is contained in the original query Q.

In the case of TGDs with terminating chase, this procedure matches our approach for SPJ-plans. The first step, chasing Q, corresponds in our setting to generating consequences using chase steps for the canonical database of  $Q_0$  with the original copy of the constraints. The second step corresponds to applying our "forward-accessibility axioms," or equivalently to taking the accessible part of the instance generated in the first step. The final step corresponds to applying the InfAccCopy constraints and checking for a match of the copy of Q.

Note that Deutsch et al. [2007] utilize the previous algorithm in the setting of their more general constraints, by defining a variant of the chase with disjunction and negation, and a notion of "answerable part" of a query that applies to USPJ queries. This extension is not subsumed by the approach in this article, since we do not deal with disjunction and negation in constraints. However, it is closely related to the approach for USPJ-plans in Benedikt et al. [2014]. The extended definition of "answerable part" to handle atomic negation corresponds to applying both the forward-accessibility axioms and a restriction of the backward-accessibility axioms, with the restriction being that all variables  $x_i$  in the atom  $R(x_1 \dots x_n)$  must satisfy accessible. This variation of the accessible schema and its relationship to USPJ-plans is investigated in Benedikt et al. [2014].

In Section 7 of Deutsch et al. [2007], the authors provide another algorithm for the problem, which proceeds by augmenting the constraints with a new set of auxiliary axioms capturing accessibility (denoted  $\Sigma_D$ ), and a derived query (denoted there as dext(Q)). The main result says that for some classes of constraints (those with "stratified witnesses"), a source query Q has an executable  $USPJ^-$  rewriting if and only if Q is contained in dext(Q) with respect to the enhanced schema. Again, in the case of TGDs with terminating chase, this coincides with our technique. Deutsch et al. [2007] emphasize the second algorithm as a way of reducing rewriting with access patterns and constraints to rewriting under constraints alone.

First-order/relational algebra rewritings, and their distinction from positive existential or SPJ rewritings, are not covered in Deutsch et al. [2007]. Nor do they consider the relationship of rewritability to semantic properties. However, the semantics-to-syntax approach we take here is related to results and discussions in Section 9 of Deutsch et al. [2007]. In Theorem 22, they prove that their notion of executable query covers all  $USPJ^-$  queries that could be implemented using the access methods. Although the

theorem is phrased using a Turing Machine model, the proof shows that every accessdetermined  $USPJ^-$  query has a rewriting that is executable in their sense. We make use of this result in our analysis of expressiveness in Section 3.

Relationship to Bárány et al. [2013]. The work of Bárány et al. [2013] deals also with integrity constraints and access patterns. Instead of plans, as here, it targets a relational algebra query that runs over the accessible part. Thus, executing a rewriting will always require exhaustively generating the accesses. It defines the notion of access determinacy used in this article and obtains tight bounds on the complexity of detecting access determinacy for constraints in guarded logics (e.g., the guarded negation fragment, inclusion dependencies). It also shows that access-determined conjunctive queries over guarded constraints always have rewritings that are in the guarded negation fragment. The distinction between relation algebra, existential, and positive existential rewriting is not studied in Bárány et al. [2013]. Indeed, it is incorrectly claimed in Bárány et al. [2013] that the notions coincide for GTGD constraints.

Comparison to Benedikt et al. [2014, 2014, 2015]. This article is an extension of the extended abstract [Benedikt et al. 2014]. That paper introduced a method for generating plans from proofs in the presence of general first-order constraints, with the general technique being based on interpolation, which we explain later. This article deals with a special case of the method, which was emphasized in Benedikt et al. [2014], in the case of constraints given by TGDs. Full proofs were not included in Benedikt et al. [2014]. The scope of several theorems has been enlarged (e.g., covering non-Boolean queries), while several new results—Theorem 4.6, concerning the collapse of USPJ-plans to SPJ-plans for TGDs, and Proposition 6.2, concerning dominance with respect to executable queries—have been added in this article.

Benedikt et al. [2014] briefly discussed heuristic optimization for search. In later work, Benedikt et al. [2015] explored methods for making the generation of proofs from plans more efficient. The demonstration paper [Benedikt et al. 2014] applies the ideas in this article to querying over web services.

Chase-based plan generation and interpolation-based plan generation. The Craig Interpolation theorem [Craig 1957] states that whenever we have first-order formulas  $\varphi_1$ ,  $\varphi_2$ , and  $\varphi_1$  entails  $\varphi_2$ , there is a formula  $\varphi$  such that

- $-\varphi_1$  entails  $\varphi$ ,  $\varphi$  entails  $\varphi_2$ , and
- $-\varphi$  uses only relation symbols occurring in both  $\varphi_1$  and  $\varphi_2$ , and only constants occurring in both  $\varphi_1$  and  $\varphi_2$ .

Such a  $\varphi$  is said to be an *interpolant* for the entailment of  $\varphi_2$  by  $\varphi_1$ .

Craig showed that interpolation could be used to transform proofs of a certain semantic property of a query into a syntactic representation that enforces that property. Craig did this for a property called "implicit definability," which is related to the notion of determinacy used in the later work of Segoufin and Vianu [2005]. This idea of using interpolation to go from "semantics to syntax" has since been applied to a number of semantic properties by logicians (e.g., Otto [2000]), but without addressing algorithmic concerns.

We explain briefly how interpolation can be used to generalize the proofs-to-plan approach we provide here. Consider the inductive algorithm given to create SPJ-plans from chase proofs, Algorithm 1. If we translate the plans to formulas, we see that the output of the algorithm is an interpolant for the entailment

$$Q \wedge \Sigma \models (\mathsf{Ax}_{\mathsf{For}} \wedge \Sigma' \to \mathsf{InfAcc} Q),$$

where  $\Sigma$  is a conjunction of the Sch constraints,  $\Sigma'$  a conjunction of the InfAccCopy constraints, and  $Ax_{For}$  a conjunction of the forward-accessibility axioms. Consider the case

22:44 M. Benedikt et al.

of "vocabulary-based restrictions," where every relation either has no access methods or is an input-free access method. The common nonschema constants are exactly the ones corresponding to free variables, and the common relations are those that have an access method. Therefore, an interpolant will be a formula using only the relations that have an access method. Thus, an interpolation algorithm can allow us to get reformulations in the vocabulary-based setting. The RA algorithm can similarly be seen as computing an interpolant for an entailment involving both forward- and backward-accessibility axioms, and for vocabulary-based restrictions such interpolants correspond to first-order reformulations over the relations that have an access.

The relationship between plan generation and interpolants suggests that an alternative approach to our results would be to prove an appropriate interpolation theorem and argue that for any access schema, the interpolants could be converted into plans. The advantage of an interpolation-based approach is that it could be applied to arbitrary first-order constraints, where chase proofs are not available. We do not have space to explain this in detail here, but such an approach is possible. One requires a proof system that generalizes the chase to arbitrary first-order constraints, and tableau proofs provide such a system. One also requires a strengthening of Craig's interpolation theorem guaranteeing that the interpolant can be converted to a plan making use of the access methods. In the conference paper [Benedikt et al. 2014], such a theorem is stated and its proof is sketched. Using this interpolation theorem, Benedikt et al. [2014] derive theorems relating semantic properties, proofs, and plans, some of them generalizing the ones given here.

Comparison with Toman and Weddell [2011]. Chapter 5 of the book of Toman and Weddell [2011] outlines an approach to reformulating queries with respect to a physical schema that is based on proofs. They discuss proofs using the chase algorithm, as well as an extended proof system connected to Craig Interpolation, remarking that the latter can synthesize plans that are not conjunctive. Access methods are not the focus of the work, but Toman and Weddell [2011] outline an approach for handling them heuristically, by postprocessing formulas so that they can be executed using the access methods.

Other related work. Several other works provide algorithms for querying in the presence of both access patterns and integrity constraints. Duschka et al. [2000] include access patterns in their Datalog-based approach to data integration. They observe, following Li [2003], that the accessible data can be "axiomatized" using recursive rules. We will make use of this axiomatization (see the "accessibility axioms" defined later on) but establish a tighter relationship between proofs that use these axioms and query plans.
