Abstract. We consider a two-player infinite game with zero-reachability objectives played on a 2-dimensional vector addition system with states (VASS), the states of which are divided between the two players. Brázdil, Jančar, and Kučera (2010) have shown that for $k > 0$, deciding the winner in a game on k-dimensional VASS is in $(k-1)$-EXPTIME. In this paper, we show that, for $k = 2$, the problem is in P, and thus improve the EXPTIME upper bound.

1. Introduction

Vector addition systems with states (VASS) is an abstract computational model equivalent to Petri nets [8] which is well suited for modelling and analysis of distributed concurrent systems. Roughly speaking, a *k-dimensional VASS*, where $k > 0$ is an automaton with a finite control and k unbounded counters which can store non-negative integers. It can be represented as a finite k-weighted directed graph $G = (V, E, w)$. For simplicity, the weights of the edges are restricted to vectors from the set $\{-1, 0, 1\}^k$, i.e., $w : E \to \{-1, 0, 1\}^k$. At the beginning of the computation, a token is placed on one of the vertices. In each step of the computation, a VASS can move the token to one of the destination vertices of the edges emanating from the current vertex with the token. This also updates the vector of current counter values by adding the weight of the traversed edge. Since the counters cannot become negative, transitions which attempt to decrease a zero counter are disabled. Configurations of a given VASS are written as pairs $(v, \overrightarrow{n})$, where v is the current vertex and $\overrightarrow{n} \in \mathbb{N}_0^k$ is a vector of the current counter values.

Brázdil, Jančar, and Kučera [2] extended VASS in two respects. First, the set of vertices is divided between two players, named $\square$ and $\lozenge$, and so we get a turn-based two-player game where the choice

---

of an outgoing edge is upon the player who owns the current vertex with the token. Second, the weights of edges may contain symbolic components (denoted by ω) whose intuitive meaning is "add an arbitrarily large non-negative integer to the appropriate counter". Edges with symbolic components represent infinite number of transitions. This two-fold extension of a VASS is called a *game on k-dim VASS*.

Games on k-dim VASS can also be thought of as an extension of energy games [4, 1], which are essentially 1-dim VASS games. The complexity of solving energy games was shown to be in $O(|V| \cdot |E| \cdot W)$, where W is the maximal absolute edge-weight [3]. Therefore, if edge-weights are restricted to $\{-1, 0, 1\}$, the problem is in P.

Games on k-dim VASS can be used for modelling various resource scheduling problems. More precisely, the counter values represent reserves of individual resources and the goal is to never run out of any resource. For example, a VASS game can be used to model a workshop producing puppets [2]. The resources are the things needed for the production of puppets: wood, fabric, wires, etc. The player $\square$ represents employees of the workshop who are trying to never run out of the resources so that they can always serve the requests of their customers. The player $\diamond$ then represents the unpredictable customers of the workshop "consuming" the puppets.

Various problems on games on k-dim VASS have been considered in [2]. In particular, the Z-reachability problem is the problem of deciding whether for a given starting configuration $(v, \overrightarrow{n})$, the player $\square$ has a strategy that ensures that not one of the k counters is ever equal to zero, which is the complement of the problem of deciding whether the player $\diamond$ has a strategy that ensures that eventually at least one of the counters is zero, i.e., a configuration $(v', (n'_1, \ldots, n'_k))$ such that $(\exists i \in \{1, \ldots, k\})(n'_i = 0)$ is reached. This problem was shown in [2] to belong to the complexity class $(k-1)$-EXPTIME. In particular, for $k = 1$ and $k = 2$, the problem is in P and EXPTIME, respectively.

Our Contribution. In this paper, we show that 2-dimensional VASS games with Z-reachability objectives are solvable in polynomial time, and thus improve the EXPTIME upper bound given in [2]. More precisely, we show that the winner in 2-dim VASS games can be decided in polynomial time, and a finite description of winning starting configurations of both players is also computable in polynomial time. This contrasts sharply with the previous results about VASS (or, equivalently, Petri nets) where the undecidability/intractability border usually lies between one and two counters. For example, k-dim VASS are equivalent to Petri nets with k unbounded places, and it has been shown that the bisimilarity problem is decidable for Petri nets with one unbounded place and undecidable for Petri nets with two or more unbounded places [6, 7]. The Z-reachability problem for games on 2-dim VASS also seems to be harder than the 1-dim case, because unlike for the games on 1-dim VASS, in games on 2-dim VASS, if we add an arbitrarily small rational number to some element of some edge-weight, then the set of vertices of G which are part of some winning configuration for $\square$ may change.

An interesting open question is whether the techniques presented in this paper can be extended to three- (or even more-) dimensional VASS games. Since the presented results about 2-dimensional VASS are relatively complicated (despite investing some effort, we did not manage to find any substantial simplifications), we suspect this problem as difficult.

The Z-reachability problem for games on k-dim VASS can be also thought of as a problem of deciding the winner in an ordinary two-player reachability game with infinite arena. The arena consists of all possible configurations $(v, \overrightarrow{n}) \in V \times \mathbb{N}_0^k$ and it is divided between $\square$ and $\diamond$ according to the first component of the configurations. The set of target configurations is the set $Z = \{(v, (n_1, \ldots, n_k)) \mid (\exists i \in \{1, \ldots, k\})(n_i = 0)\}$. $\square$ wants to avoid the set Z while $\diamond$ wants to reach it. We note that the game is upward-closed in the sense that if $\square$ has a strategy to win from a configuration $(v, \overrightarrow{n}) \in V \times \mathbb{N}_0^k$, then the same strategy also wins each play starting from

$(v, \overrightarrow{n}') \in V \times \mathbb{N}_0^k$ such that $\overrightarrow{n}' \geq \overrightarrow{n}$. Therefore, there is a finite set of minimal winning starting configurations.

The key part of our proof for games on 2-dim VASS is showing that for each vertex from which $\square$ can win, each pair of minimal sufficient initial counter values (a, b) satisfies $a, b \leq m \cdot |V|^n$, where $m, n \in \mathbb{N}$ are some fixed constants. Therefore, the game can be solved by a reduction to a reachability game with finite arena of polynomial size with respect to $|V|$. The infinite arena described in the previous paragraph can be made finite by collapsing configurations with too high counter values. More precisely, if $(v, (a, b))$ is such that (a, b) are minimal sufficient initial counter values for plays starting from v, then the whole set of configurations $\{(v, (a', b')) \mid a' \geq a \wedge b' \geq b\}$ can be collapsed to the configuration $(v, (a, b))$. This bounds the arena from above, and since all minimal sufficient initial counter values are polynomial we get an arena of polynomial size. Since reachability games can be solved in polynomial time with respect to the size of their arena, we get the desired result.

In the following section, we give some additional necessary definitions and then we get to the actual proof.

2. Preliminaries

For technical convenience, we will define the game in a slightly different way than in Section 1, and then we will show how the properties of the modified game imply existence of a polynomial algorithm for solving the original game. The properties of the modified game are proved in Section 3, the main part of this paper.

A *game on 2-dim vector addition system with states (VASS)* is a tuple $\Gamma = (G, V_\square, V_\Diamond)$, where $G = (V, E, w)$ is a finite two-weighted directed graph such that V is a disjoint union of the sets $V_\square$ and $V_\Diamond$, $E \subseteq V^2$, $w : E \to \{-1, 0, 1\}^2$, and each vertex has at least one outgoing edge. The graph G can also be thought of as a 2-dim VASS [5]. The game is played by two opposing players, named $\square$ and $\Diamond$. At the beginning of a play a pair of constants $(a, b) \in \mathbb{N}_0^2$ is given, the actual play then starts by placing a token on some given vertex and the players move the token along the edges of G ad infinitum. If the token is on vertex $v \in V_\square$, $\square$ moves it. If the token is on vertex $v \in V_\Diamond$, $\Diamond$ moves it. This way an infinite path $p_\infty = (v_0, v_1, v_2, \dots)$ is formed. The path p_∞ is also called a *play*. The play is winning for $\square$, if the components of the sum of the weights of the traversed edges are above $(-a, -b)$ during the whole play, i.e., $(\forall k \in \mathbb{N}_0)(\sum_{i=0}^{k-1} w(v_i, v_{i+1}) \geq (-a, -b))$ where the sum and the inequality are element-wise. The play is winning for $\Diamond$, if there is a point in the play where at least one of the components of the sum of the traversed edges is below the corresponding constant, i.e., $(\exists k \in \mathbb{N}_0)(\sum_{i=0}^{k-1} w_1(v_i, v_{i+1}) < -a \vee \sum_{i=0}^{k-1} w_2(v_i, v_{i+1}) < -b)$. Please note that the initial vector of counter values is $(0, 0)$ and the counters are allowed to go negative.

A *strategy* of $\square$ is a function $\sigma : V^* \cdot V_\square \to V$ such that for each finite path $p = (v_0, \dots, v_k)$ with $v_k \in V_\square$, it holds that $(v_k, \sigma(p)) \in E$. Recall that each vertex has out-degree at least one, and so the definition of a strategy is correct. The set of all strategies of $\square$ in Γ is denoted by Σ^Γ. We say that an infinite path $p_\infty = (v_0, v_1, v_2, \dots)$ agrees with the strategy $\sigma \in \Sigma^\Gamma$ if for each $v_i \in V_\square$, $\sigma(v_0, \dots, v_i) = v_{i+1}$. A strategy π of $\Diamond$ is defined analogously. The set of all strategies of $\Diamond$ in Γ is denoted by Π^Γ. Given an initial vertex $v \in V$, the *outcome* of two strategies $\sigma \in \Sigma^\Gamma$ and $\pi \in \Pi^\Gamma$ is the (unique) infinite path $\mathsf{outcome}^\Gamma(v, \sigma, \pi) = (v = v_0, v_1, v_2, \dots)$ that agrees with both σ and π.

The set V can be partitioned into two sets, $W_\square$ and $W_\Diamond$, so that if the play starts at some vertex $v \in W_\square$, then for some $(a, b) \in \mathbb{N}_0^2$, $\square$ has a strategy that ensures that he will win, and if the play starts at some vertex $v \in W_\Diamond$, then for any $(a, b) \in \mathbb{N}_0^2$, $\Diamond$ has a strategy that ensures that she will

win [2]. Formally:

$$v \in W_\square \Leftrightarrow \quad (\exists a, b \in \mathbb{N}_0)(\exists \sigma \in \Sigma^\Gamma)(\forall \pi \in \Pi^\Gamma) \tag{1}$$
$$(\forall k \in \mathbb{N}_0)(\textstyle\sum_{i=0}^{k-1} w(v_i, v_{i+1}) \geq (-a, -b))$$

where $v_0 = v$ and $(v_0, v_1, v_2, \dots) = \mathsf{outcome}^\Gamma(v, \sigma, \pi)$. To solve the game is to determine the sets $W_\square$ and $W_\Diamond$. In this paper, we will show that there is a constant $K \in \mathbb{N}_0$ of *polynomial size* with respect to $|V|$ such that for each $v \in W_\square$, the constants a, b in (1) can always be chosen so that $a, b \leq K$. By the statement that $K \in \mathbb{N}_0$ is of polynomial size with respect to $|V|$, we mean that $K \leq m \cdot |V|^n$ for some fixed constants $m, n \in \mathbb{N}$.

The polynomial size of K implies that the values of both counters in all minimal winning configurations of $\square$ in the original reachability game with infinite arena are of polynomial size with respect to $|V|$ (cf. Section 4). It follows that we can obtain the solution of the original game by solving only a restricted game, where the values of both counters are bounded by a number of polynomial size with respect to $|V|$. Since a reachability game can be solved in polynomial time with respect to the number of its configurations, we have a polynomial-time algorithm for solving the original reachability game with infinite arena. Our definition of the game on 2-dim VASS does not consider edge-weights with the symbolic component ω. We outline how to extend the proofs to games with symbolic components in edge-weights in Section 5.

If $e \in E$, then $w_1(e)$ is the first component of $w(e)$ and $w_2(e)$ is the second component of $w(e)$, i.e., $w(e) = (w_1(e), w_2(e))$. A simple cycle in G is a cycle with no repeated vertex. In this paper, we will work only with simple cycles, and so we will often omit the adjective "simple". If $c = (v_0, \dots, v_{k-1}, v_k = v_0)$ is a cycle, then $w(c)$ is the sum of the weights of its edges, element-wise, i.e., $w(c) = (\sum_{i=0}^{k-1} w_1(v_i, v_{i+1}), \sum_{i=0}^{k-1} w_2(v_i, v_{i+1}))$. The terms $w_1(c)$ and $w_2(c)$ have the intuitive meaning. Because of the limitations on the weights of the edges, it always holds that $|w_1(c)|, |w_2(c)| \leq |V|$, for each cycle c in G. The weight of a path $(v_0, \dots, v_k)$ is defined analogically.

The cycles of G can be partitioned into four sets. The first set, P, is the set of cycles c such that $w_1(c) \geq 0 \wedge w_2(c) \geq 0$. The second set, N, is the set of cycles c such that $(w_1(c) \leq 0 \wedge w_2(c) < 0) \vee (w_1(c) < 0 \wedge w_2(c) \leq 0)$. The third set, A, is the set of cycles c such that $w_1(c) > 0 \wedge w_2(c) < 0$. Finally, the fourth set, B, is the set of cycles such that $w_1(c) < 0 \wedge w_2(c) > 0$.

The ratio of the weights of a cycle c is the fraction $\frac{w_1(c)}{w_2(c)}$. We will use $\mathcal{R}$ to denote the set of all possible ratios of weights of the cycles from $A \cup B$, i.e., $\mathcal{R} = \{\frac{a}{b} \mid a \in \{-|V|, \dots, -1\} \wedge b \in \{1, \dots, |V|\}\}$. For each $X \in \{A, B\}$, $\sim \in \{<, \leq, =, \geq, >\}$, and $R \in \mathcal{R}$, we will use $X_{\sim R}$ to denote the set of cycles $\{c \in X \mid \frac{w_1(c)}{w_2(c)} \sim R\}$.

Let $\Gamma = (G = (V, E, w), V_\square, V_\Diamond)$ be a game on 2-dim VASS such that $W_\square \neq \emptyset$, and let $v \in W_\square$. We can define the following finite directed tree rooted at v. $T^{\Gamma, v} = (T_V^{\Gamma, v}, T_E^{\Gamma, v})$, where

$$T_V^{\Gamma, v} = \{(v_0, v_1, \dots, v_k) \mid \quad v_0 = v \wedge$$
$$(v_0, v_1, \dots, v_k) \text{ is a path in } G \wedge$$
$$(\forall 0 \leq i < j < k)(v_i \neq v_j) \wedge$$
$$(\forall 0 \leq i < k)(v_i \in W_\square) \}$$

That is, the set of nodes of the tree is the set of paths in G starting from v, with no repeated vertices and no vertices from $W_\Diamond$, with the possible exception of the last vertices in the paths. Please note that the leaves in the tree are the paths ending either at the first repeated vertex or at the first vertex from

$\Diamond$'s winning region. If $p = (v_0, \ldots, v_k) \in T_V^{\Gamma, v}$, then $\mathsf{last}(p)$ is defined to be v_k. We define the depth of a node $p = (v_0, \ldots, v_k) \in T_V^{\Gamma, v}$ as $\mathsf{h}(p) = k$.

There is an edge $((v_0, \ldots, v_k), (u_0, \ldots, u_l)) \in T_E^{\Gamma, v}$ if and only if $l = k + 1$, for each $i \in \{0, \ldots, k\}$, $v_i = u_i$, and $(v_k, u_l) \in E$. If the game Γ is clear from the context, then the tree is denoted simply T^v. The set of nodes, T_V^v, is divided into inner nodes and leaves. The leaves of the tree are the nodes with no successors.

Let $q = (v_0, \ldots, v_k)$ be a leaf. If $\mathsf{last}(q) \notin W_\Diamond$, then $\mathsf{ce}(q) = (v_i, \ldots, v_k)$, $\mathsf{rh}(q) = i$, and $\mathsf{ph}(q) = (v_0, \ldots, v_i)$, where $i < k$ such that $v_i = v_k$. That is, $\mathsf{ce}(q)$ is the cycle closed at v_k, $\mathsf{rh}(q)$ is the depth of the node at which the closed cycle starts, and $\mathsf{ph}(q)$ is the path from the root to the starting vertex of the cycle. It holds that $\mathsf{rh}(q) = \mathsf{h}(\mathsf{ph}(q))$.

For the whole paper, let $\Gamma = (G = (V, E, w), V_\square, V_\Diamond)$ be a game on 2-dim VASS. The elements of V will be called vertices. For each $v \in W_\square$, the elements of T_V^v will be called nodes, inner nodes, leaves, or, when it is convenient, paths, because they are paths in G. We suppose that $|V| > 1$. For $|V| = 1$ the game is very simple to solve: There is only one vertex v with a self-loop, and so $v \in W_\square$ if and only if the self-loop is in the set P.

3. Main Result

We prove that there is a constant $K \in \mathbb{N}_0$ such that $K \leq m \cdot |V|^n$ for some fixed constants $m, n \in \mathbb{N}$, and for each $v \in W_\square$, $\square$ has a strategy σ such that for each play $(v = v_0, v_1, v_2, \ldots)$ agreeing with σ, it holds that $(\forall k \in \mathbb{N}_0)(\sum_{i=0}^{k-1} w(v_i, v_{i+1}) \geq (-K, -K))$. This implies that $(v, (K, K))$ is a winning initial configuration for $\square$ in the original game. Actually, only the configuration $(v, (K+1, K+1))$ is winning for sure, because $\square$ has to keep the counters strictly positive if he wants to win in the original game, but for simplicity we will take the liberty to omit the "+1". In Section 4, we will show that the configuration $(v, (K, K))$ being winning for $\square$ implies that *each minimal* winning configuration for $\square$, $(v, (a, b))$, has $(a, b) \leq ((|V| + 1) \cdot K, (|V| + 1) \cdot K)$. This in turn implies that the 2-dim VASS game can be solved by reduction to a reachability game with a finite arena of polynomial size with respect to $|V|$, as described in detail in Section 4. For reachability games there are polynomial-time algorithms, and so 2-dim VASS games can be solved in polynomial time. So, let's prove that there is a constant K with the above properties. We first give an outline of the proof and then prove it formally.

3.1. Proof Outline

Each prefix $p_\infty^k = (v_0, \ldots, v_k)$ of an infinite path $p_\infty = (v_0, v_1, v_2, \ldots)$ in G can be partitioned using the following procedure: Start at v_0 and go along the path until an already visited vertex is encountered, then remove the closed cycle, leaving only the first vertex of the cycle, and continue in the same fashion. This way, p_∞^k is partitioned into a set of cycles $c_1, \ldots, c_l$ and a remaining path with no repeated vertex. If for each $i \in \{0, \ldots, k\}$, it holds that $v_i \in W_\square$, then the partitioning corresponds to a traversal of the tree T^{v_0} in the following sense. The traversal starts at $(v_0) \in T_V^{v_0}$. When a leaf q is reached, $\mathsf{ce}(q)$ is added to the set of traversed cycles and the traversal continues at $\mathsf{ph}(q)$ until a node $p \in T_V^{v_0}$ such that $\mathsf{last}(p) = v_k$ is reached. The path p is the remaining path. The partitioning of paths into simple cycles plays a crucial role in our proof.

It is easy to see that if $\square$ can ensure that only simple cycles from P are traversed, then he can win. However, this is not the only way he can win. $\square$ can also win if he is able to balance the cycles from A and B. The cycles from A increase the first counter and decrease the second counter, and the cycles from B decrease the first counter and increase the second counter. What is important are the ratios
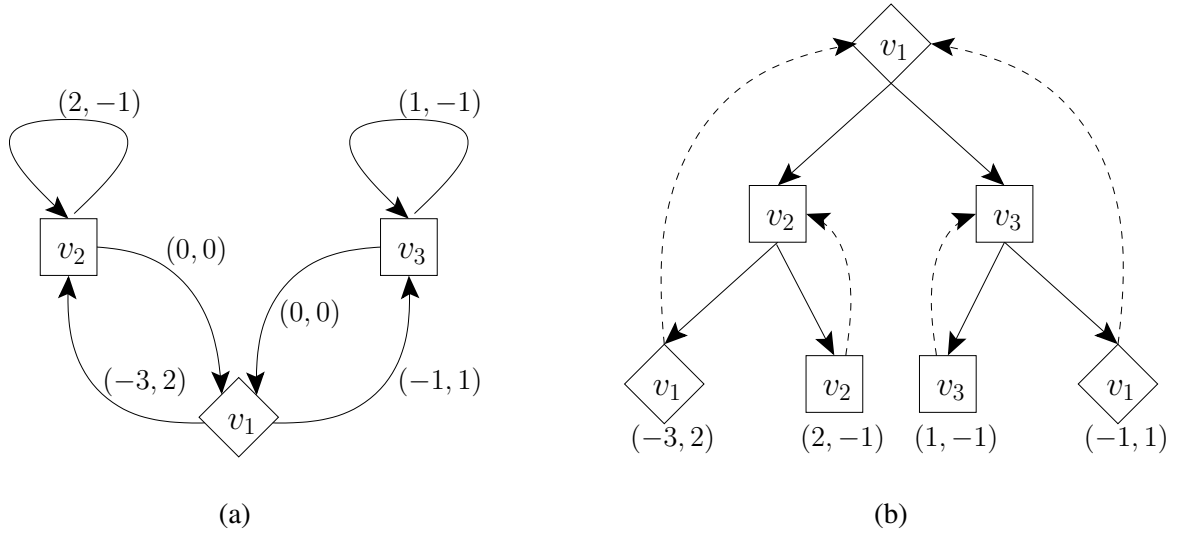

Figure 1.   The player $\square$ can ensure that only cycles from $A_{\leq R} \cup B_{\geq R} \cup P$ are traversed, for any $R \in \mathcal{R}$:
(a) example game (b) tree T^{v_1}

of the first and the second weights of the simple cycles. If $c_1 \in A$ and $c_2 \in B$ are the only simple
cycles that can be traversed, and $\square$ is able to alternate them arbitrarily, then he can win if and only
if $\frac{w_1(c_1)}{w_2(c_1)} \leq \frac{w_1(c_2)}{w_2(c_2)}$, or, equivalently $w_1(c_1)w_2(c_2) \geq w_1(c_2)w_2(c_1)$. Moreover, he can alternate the
cycles in such a way that both counters are always greater or equal to $-|V|$. Please note, that the set of
all possible ratios of cycles in G from A and B is a subset of $\mathcal{R}$, and so it has at most $|V|^2$ elements.

If $v \in W_\square$, then for each $R \in \mathcal{R}$, for a play starting at v, $\square$ can ensure that only cycles from
$A_{\leq R} \cup B_{\geq R} \cup P$ are traversed. This does not mean that $\square$ can ensure that all these three types of
cycles are traversed, we only claim that $\square$ can ensure that each traversed cycle is from $A_{\leq R}$ or $B_{\geq R}$
or P. For example, consider the following game.

In Figure 1 (a), there is a 2-dim VASS game with three vertices v_1, v_2, v_3, where $v_1 \in V_\Diamond$ and
$v_2, v_3 \in V_\square$. Please note that not all the edge weights are from $\{-1, 0, 1\}^2$, but this is not a problem.
You may thing of the edge (v_1, v_2), for instance, as an abbreviation for the path (v_1, u_1, u_2, v_2), where
u_1, u_2 are auxiliary vertices, and $w(v_1, u_1) = (-1, 0)$, $w(u_1, u_2) = w(u_2, v_1) = (-1, 1)$. Let's first
show that all vertices in the game belong to $W_\square$.

There are four cycles in the game: $c_1 = (v_1, v_2, v_1)$, $c_2 = (v_2, v_2)$, $c_3 = (v_1, v_3, v_1)$, $c_4 =
(v_3, v_3)$, where $c_1, c_3 \in B$ and $c_2, c_4 \in A$. It holds that $w(c_1) = (-3, 2)$, $w(c_2) = (2, -1)$, $w(c_3) =
(-1, 1)$, and $w(c_4) = (1, -1)$. Let's denote the ratios of the cycles c_1, c_2, c_3, and c_4 by b_1, a_1, b_2, a_2,
respectively. It holds that $b_1 = -\frac{3}{2}$, $a_1 = -2$, $b_2 = -1$, $a_2 = -1$. Since $a_1 \leq b_1$, it follows that the
cycles c_1 and c_2 balance each other. The same goes for the cycles c_3 and c_4. Let's say that a play starts
from v_1. If $\square$ wants to win, then the vertex v_1 must be visited infinitely many times, because otherwise
the second counter goes to $-\infty$. Therefore, each play potentially winning for $\square$ can be written as
$p = (v_1, \ldots, v_1, \ldots, v_1, \ldots)$. The play can be divided into two sub-plays. The first subplay $p^1 =
(v_1, v_2, \ldots, v_1, v_2, \ldots, v_1, v_2, \ldots)$, i.e., it contains the segments $(v_1, v_2, \ldots, v_1)$ of the original play
where $\Diamond$ chooses the edge (v_1, v_2). The second sub-play is $p^2 = (v_1, v_3, \ldots, v_1, v_3, \ldots, v_1, v_3, \ldots)$.
Please note that either p^1 or p^2 can be finite, but not both. Without loss of generality, let's suppose
that both p^1 and p^2 are infinite. Since the cycles c_1 and c_2 balance each other, $\square$ has a strategy
such that there is $(a^1, b^1) \in \mathbb{N}_0^2$ such that $(\forall k \in \mathbb{N}_0)(\sum_{i=0}^{k-1} w(u_i^1, u_{i+1}^1) \geq (-a^1, -b^1))$, where

$p^1 = (u_0^1, u_1^1, u_2^1, \dots)$. Similarly, there is a pair of constants (a^2, b^2) for the sub-play p^2. It follows that in the original play p, the counters never go below $(-a^1 - a^2, -b^1 - b^2)$. Therefore, $\square$ has a winning strategy form v_1, hence $v_1 \in W_\square$. The fact that also $v_2, v_3 \in W_\square$ follows easily. The technique we just presented is the main idea of the EXPTIME complexity proof in [2] - each $\lozenge$'s vertex doubles the estimate of sufficient initial counter values and since for a game with only $\square$'s vertices, the estimate is polynomial, we get an exponential bound. Now that we know that $v_1, v_2, v_3 \in W_\square$, let's show that for each $R \in \mathcal{R}$, $\square$ is able to ensure that only cycles from $A_{\leq R} \cup B_{\geq R} \cup P$ are traversed.

The set of ratios of all cycles in the game in Figure 1 (a) is $\{a_1, b_1, a_2, b_2\} = \{-2, -\frac{3}{2}, -1\}$, so it makes sense to consider the following cases for R.

$R < -2$	If $\lozenge$ chooses the edge (v_1, v_2), then $\square$ goes back to v_1 (traversing the cycle $c_1 \in B_{\geq R}$). If $\lozenge$ chooses the edge (v_1, v_3), then $\square$ goes back to v_1 (traversing the cycle $c_3 \in B_{\geq R}$).
$-2 \leq R \leq -\frac{3}{2}$	If $\lozenge$ chooses the edge (v_1, v_2), then $\square$ has two options. Either go back to v_1 (traversing the cycle $c_1 \in B_{\geq R}$), or traverse the cycle $c_2 \in A_{\leq R}$. If $\lozenge$ chooses the edge (v_1, v_3), then $\square$ goes back to v_1 (traversing the cycle $c_3 \in B_{\geq R}$).
$-\frac{3}{2} < R < -1$	If $\lozenge$ chooses the edge (v_1, v_2), then $\square$ traverses the cycle $c_2 \in A_{\leq R}$. If $\lozenge$ chooses the edge (v_1, v_3), then $\square$ goes back to v_1 (traversing the cycle $c_3 \in B_{\geq R}$).
$R = -1$	If $\lozenge$ chooses the edge (v_1, v_2), then $\square$ traverses the cycle $c_2 \in A_{\leq R}$. If $\lozenge$ chooses the edge (v_1, v_3), then $\square$ has two options. Either go back to v_1 (traversing the cycle $c_3 \in B_{\geq R}$), or traverse the cycle $c_4 \in A_{\leq R}$.
$R > -1$	If $\lozenge$ chooses the edge (v_1, v_2), then $\square$ traverses the cycle $c_2 \in A_{\leq R}$. If $\lozenge$ chooses the edge (v_1, v_3), then $\square$ traverses the cycle $c_4 \in A_{\leq R}$.

To sum up, in all the cases, $\square$ can ensure that only cycles from $A_{\leq R} \cup B_{\geq R} \cup P$ are traversed. To see why the claim holds in general, recall that each play in Γ starting at v corresponds to a traversal of the tree T^v. Figure 1 (b), there is the tree T^{v_1} for the example game in Figure 1 (a). Reaching a leaf in the tree corresponds to closing of a cycle, the weights of the cycles are next to the appropriate leaves. The points where the play continues after reaching a leaf are indicated by dotted arrows. Let's now consider a general game Γ.

Let $v \in W_\square$ and $R \in \mathcal{R}$, then $\square$ can ensure that all reached leaves in T^v correspond to cycles from $A_{\leq R} \cup B_{\geq R} \cup P$, because if $\lozenge$ could ensure that a leaf q such that $\mathsf{ce}(q) \in A_{>R} \cup B_{<R} \cup N$ is reached, then she would be able to ensure that *all* reached leaves in a play correspond to a cycle from $\mathsf{ce}(q) \in A_{>R} \cup B_{<R} \cup N$ (Recall that if a leaf q is reached, then the play continues at $\mathsf{ph}(q)$). Therefore, if the play is long enough, then at least one of the counters goes below an arbitrary constant. We omitted the possibility that a leaf q such that $\mathsf{last}(q) \in W_\lozenge$ is reached, because if such a leaf is reached, then $\lozenge$ can also win.

Unfortunately, the strategy of $\square$, σ_R^v, that ensures that all traversed cycles are from $A_{\leq R} \cup B_{\geq R} \cup P$ may not be the sought strategy, because it may not be winning for $\square$. The reason is that he may not be able to alternate the cycles from $A_{\leq R}$ and $B_{\geq R}$ so that both counters are always above some constant. For example, $\lozenge$ may be able to ensure that out of the cycles from $A_{\leq R} \cup B_{\geq R} \cup P$, only cycles from $A_{\leq R}$ are traversed, and so the second counter goes to $-\infty$. However, the sought strategy for $\square$ can

be assembled from the strategies σ_R^v for all $v \in W_\square$ and $R \in \mathcal{R}$, albeit we may have to select a much greater number than $|V|$ as the constant K, but still polynomial with respect to $|V|$. The sought strategy is assembled in the following way.

Let $v \in W_\square$ be the starting vertex. We select $R \in \mathcal{R}$ arbitrarily, and start using the strategy σ_R^v. We are using the strategy σ_R^v until there is a certain "imbalance" between the cycles from $A_{\leq R}$ and the cycles from $B_{\geq R}$. Let u be the current vertex when the imbalance occurs. If too many cycles from $A_{\leq R}$ were traversed, then we change the current strategy to $\sigma_{R'}^u$ if the imbalance was caused by cycles from $A_{=R'}$ where $R' < R$, and if too many cycles from $B_{\geq R}$ were traversed, then we change the current strategy to $\sigma_{R''}^u$ such that the imbalance was caused by cycles from $B_{=R''}$ where $R'' > R$. These changes of strategy ensure that for each ratio, the cycles with that ratio can contribute to an overall imbalance between the cycles from A and B "only once". The precise definition of a contribution to the overall imbalance (it must be polynomial somehow) and the precise rules for the strategy changing will be given later. Before we get to the formal proof, one additional point has to be discussed.

From the previous paragraph, it follows that it is not enough that the strategy σ_R^v traverses only cycles from $A_{<R} \cup B_{>R} \cup P$. It must also be able to balance the cycles from $A_{=R}$ and $B_{=R}$, so that an imbalance between $A_{<R}$ and $B_{>R}$ is never caused by the cycles from $A_{=R}$ or $B_{=R}$. Therefore, the strategy σ_R^v we will define guarantees that only cycles from $A_{<R} \cup B_{>R} \cup P$ are traversed and the traversed cycles from $A_{=R}$ or $B_{=R}$ are kept in balance. The balance will not be the best possible as if we were able to alternate the cycles arbitrarily, but it will be such that the sum of the weights of the traversed cycles from $A_{=R} \cup B_{=R}$ is always greater or equal to $(-2 \cdot |V|^2, -2 \cdot |V|^2)$. This "balancing property" also ensures that if $R = \min \mathcal{R}$, then only the cycles from $B_{>R}$ can cause an imbalance, and if $R = \max \mathcal{R}$, then only the cycles from $A_{<R}$ can cause an imbalance.

3.2.   Formal Proof

We will first define the "local" strategies for each $v \in W_\square$ and $R \in \mathcal{R}$, and then we will assemble the "global" strategy from the local strategies. So let $v \in W_\square$, $R \in \mathcal{R}$, and consider the tree T^v.

To define a local strategy, we introduce a valuation of the nodes of the tree T^v. Recall that a play starting from v corresponds to a traversal of the tree T^v. Roughly speaking, the valuation we define says which types of cycles can be forced from each node of the tree. The local strategy will decide based on the valuation.

We define values of the nodes of the tree T^v: $\mathsf{value} : T_V^v \to \{-1, 0, \ldots, |V|\}^2 \cup \{\mathbf{0}, \mathbf{1}\}$.

The values are defined recursively. The values of leaves are defined as follows. Let $q = (v_0, \ldots, v_k) \in T_V^v$ be a leaf.

$$\mathsf{value}(q) = \begin{cases} \mathbf{0} & \text{if} \quad \mathsf{last}(q) \in W_\lozenge \\ \mathbf{0} & \text{if} \quad \mathsf{last}(q) \in W_\square \wedge \mathsf{ce}(q) \in N \cup A_{>R} \cup B_{<R} \\ \mathbf{1} & \text{if} \quad \mathsf{last}(q) \in W_\square \wedge \mathsf{ce}(q) \in P \cup A_{<R} \cup B_{>R} \\ (\mathsf{rh}(q), -1) & \text{if} \quad \mathsf{last}(q) \in W_\square \wedge \mathsf{ce}(q) \in A_{=R} \\ (-1, \mathsf{rh}(q)) & \text{if} \quad \mathsf{last}(q) \in W_\square \wedge \mathsf{ce}(q) \in B_{=R} \end{cases} \tag{2}$$

To define the value of an inner node $p = (v_0, \ldots, v_k) \in T_V^v$, we introduce some notation:

$$\mathsf{amin}(p) = \min\{a \mid (\exists(p, q) \in T_E^v)(\mathsf{value}(q) = (a, b))\}$$

$$\mathsf{bmin}(p) = \min\{b \mid (\exists(p, q) \in T_E^v)(\mathsf{value}(q) = (a, b))\}$$

$$\mathsf{amax}(p) = \max\{a \mid (\exists(p,q) \in T_E^v)(\mathsf{value}(q) = (a,b))\}$$

$$\mathsf{bmax}(p) = \max\{b \mid (\exists(p,q) \in T_E^v)(\mathsf{value}(q) = (a,b))\}$$

If there is no successor of p with value from $\{-1,0,\ldots,|V|\}^2$, i.e., all successors have the value $\mathbf{0}$ or $\mathbf{1}$, then $\mathsf{amin}(p) = \mathsf{bmin}(p) = \infty$ and $\mathsf{amax}(p) = \mathsf{bmax}(p) = -\infty$. If $\mathsf{last}(p) \in V_\square$, then $\mathsf{value}(p)$ is defined as follows.

$$\mathsf{value}(p) = \begin{cases} \mathbf{0} & \text{if} & (\forall(p,q) \in T_E^v)(\mathsf{value}(q) \neq \mathbf{1}) \wedge \\ & & (\mathsf{amin}(p) \geq \mathsf{h}(p) \vee \mathsf{bmin}(p) \geq \mathsf{h}(p)) \\ (\mathsf{amin}(p), \mathsf{bmin}(p)) & \text{if} & (\forall(p,q) \in T_E^v)(\mathsf{value}(q) \neq \mathbf{1}) \wedge \\ & & \mathsf{amin}(p) < \mathsf{h}(p) \wedge \mathsf{bmin}(p) < \mathsf{h}(p) \\ \mathbf{1} & \text{if} & (\exists(p,q) \in T_E^v)(\mathsf{value}(q) = \mathbf{1}) \end{cases} \quad (3)$$

If $\mathsf{last}(p) \in V_\Diamond$, then $\mathsf{value}(p)$ is defined as follows.

$$\mathsf{value}(p) = \begin{cases} \mathbf{1} & \text{if} & (\forall(p,q) \in T_E^v)(\mathsf{value}(q) = \mathbf{1}) \\ (\mathsf{amax}(p), \mathsf{bmax}(p)) & \text{if} & (\forall(p,q) \in T_E^v)(\mathsf{value}(q) \neq \mathbf{0}) \wedge \\ & & -\infty < \mathsf{amax}(p), \mathsf{bmax}(p) < \mathsf{h}(p) \\ \mathbf{0} & \text{if} & (\exists(p,q) \in T_E^v)(\mathsf{value}(q) = \mathbf{0}) \vee \\ & & \mathsf{amax}(p) \geq \mathsf{h}(p) \vee \mathsf{bmax}(p) \geq \mathsf{h}(p) \end{cases} \quad (4)$$

The cycles from $N \cup A_{>R} \cup B_{<R}$ are called *bad cycles*. The cycles from $P \cup A_{<R} \cup B_{>R}$ are called *good cycles*. The cycles from $A_{=R} \cup B_{=R}$ are not given any special name.

How the valuation is used to define a local strategy of $\square$ is described in Section 3.4, and how the the local strategies are used to define the global strategy is described in Section 3.5. But before we get to that, we will show, in the next section, that the value of the root $(v) \in T_V^v$ is either $\mathbf{1}$ or $(-1,-1)$ (Please note that if $\mathsf{value}((v)) = (a,b)$, then the condition $a,b < \mathsf{h}((v)) = 0$ implies $a = b = -1$). We will show this by proving that if $\mathsf{value}((v)) = \mathbf{0}$, then $\Diamond$ has a winning strategy, which is in contradiction with $v \in W_\square$. From the fact that the root has value $\mathbf{1}$ or $(-1,-1)$, we will infer, in the following section, a strategy for $\square$ that ensures that only cycles from $A_{\leq R} \cup B_{>R} \cup P$ are traversed, and the cycles from $A_{=R}$ and $B_{=R}$ are kept in balance. So, let's first prove that the value of the root cannot be $\mathbf{0}$.

3.3.   The Value of the Root of T^v is Either 1 or $(-1,-1)$

We will first give a sketch of the proof and then the whole formal proof. We will use a proof by contradiction. We will suppose that $\mathsf{value}((v)) = \mathbf{0}$ and show that $\Diamond$ has a strategy that ensures that for each $K \in \mathbb{N}_0$, the first counter or the second counter will eventually go below $-K$. The strategy is outlined below.

If $\mathsf{value}((v)) = \mathbf{0}$, then $\Diamond$ has a strategy that ensures that only cycles from $A_{>R} \cup B_{<R} \cup N$ are traversed or a leaf $q \in T_V^v$ such that $\mathsf{last}(q) \in W_\Diamond$ is reached. Moreover, she can choose the strategy in such a way that whenever a node p such that $\mathsf{value}(p) = \mathbf{0}$ is visited, then either the strategy ensures that if the next reached leaf r has $\mathsf{ce}(r) \in A_{=R} \cup B_{=R}$, then $\mathsf{ce}(r) \in A_{=R} \wedge \mathsf{rh}(r) \geq \mathsf{h}(p)$, or the strategy ensures that if the next reached leaf r has $\mathsf{ce}(r) \in A_{=R} \cup B_{=R}$, then $\mathsf{ce}(r) \in B_{=R} \wedge \mathsf{rh}(r) \geq \mathsf{h}(p)$. This allows $\Diamond$ to prevent $\square$ from alternating cycles from $A_{=R}$ and $B_{=R}$. We note that $\square$ may be able to perform a few alternations, because he can sometimes prevent $\Diamond$ from forcing the chosen

kind of cycle, but only at the cost of visiting another node with value **0** that is deeper, and since the maximal depth is $|V|$, this cannot be repeated infinitely many times. Actually, $\square$ may be able to perform infinite number of alternations, but at the cost of traversing a bad cycle infinitely many times.

To sum up, $\Diamond$ has a strategy that ensures that exactly one of the following four things happens. First, a leaf q such that $\mathsf{last}(q) \in W_\Diamond$ is reached. Second, only leaves q corresponding to bad cycles or cycles from $A_{=R} \cup B_{=R}$ are reached, and a bad cycle is traversed infinitely many times. Third, there is a point from which onwards all reached leaves q have $\mathsf{ce}(q) \in A_{=R}$. Fourth, there is a point from which onwards all reached leaves q have $\mathsf{ce}(q) \in B_{=R}$. For the last three possibilities, at least one of the counters goes below arbitrary constant. For the first possibility, $\Diamond$ can apply her winning strategy from $\mathsf{last}(q) \in W_\Diamond$, and so at least one of the counters goes below arbitrary constant too. The whole formal proof follows.

First, we will define a strategy π of $\Diamond$ based on the fact that $\mathsf{value}((v)) = \mathbf{0}$, and then we will prove that it is winning for $\Diamond$. The strategy is defined below.

Let's consider a general situation, where we are at the node $p = (v = v_0, \ldots, v_k)$ such that $\mathsf{last}(p) \in V_\Diamond$ and p is not a leaf. Let further $s = (v_0, \ldots, v_i)$ such that $i = \max\{j \mid j \le k \wedge \mathsf{value}((v_0, \ldots, v_j)) = \mathbf{0}\}$. Since $\mathsf{value}((v)) = \mathbf{0}$, such an i must exist. In the following, we will use the notation $s = \mathsf{deepestzero}(p)$. At the nodes with value **0** such that $\Diamond$ cannot force a successor with value **0**, she has to make a choice whether to force a cycle from $A_{=R}$ or $B_{=R}$. Moreover, at the same node she always has to make the same choice, because she wants to prevent $\square$ from alternating cycles from $A_{=R}$ and $B_{=R}$. She also has to stick to the choice until a node with different $\mathsf{deepestzero}()$ is visited. Therefore, at p, $\Diamond$ makes decisions based on $s = \mathsf{deepestzero}(p)$. Let's consider two cases.

First case, $\mathsf{last}(s) \in V_\square$. In this case, s has no successors with value **1** and (i) all the successors have the value **0** or (ii) all the successors with two-component value have the first component greater or equal to $\mathsf{h}(s)$ or (iii) all the successors with two-component value have the second component greater or equal to $\mathsf{h}(s)$. All these facts follow from (3). We define the following evaluation procedure of s:

$$
eval_\square(s) = \begin{cases}
(i) & \text{if} & (\forall(s,q) \in T_E^v)(\mathsf{value}(q) = \mathbf{0}) \\
(ii) & \text{if} & (\exists(s,q) \in T_E^v)(\mathsf{value}(q) \ne \mathbf{0}) \wedge \\
& & (\forall(s,q) \in T_E^v)(\mathsf{value}(q) = (a,b) \Rightarrow a \ge \mathsf{h}(s)) \\
(iii) & \text{if} & (\exists(s,q) \in T_E^v)(\mathsf{value}(q) \ne \mathbf{0}) \wedge \\
& & (\exists(s,q) \in T_E^v)(\mathsf{value}(q) = (a,b) \wedge a < \mathsf{h}(s)) \wedge \\
& & (\forall(s,q) \in T_E^v)(\mathsf{value}(q) = (a,b) \Rightarrow b \ge \mathsf{h}(s))
\end{cases}
\tag{5}
$$

Second case, $\mathsf{last}(s) \in V_\Diamond$. In this case, (i) there is a successor with value **0** or (ii) there is a successor with two-component value such that the first component is greater or equal to $\mathsf{h}(s)$ or (iii) there is a successor with two-component value such that the second component is greater or equal to $\mathsf{h}(s)$. All these facts follow from (4). We define the following evaluation procedure of s:

$$
eval_\Diamond(s) = \begin{cases}
(i) & \text{if} & (\exists(s,q) \in T_E^v)(\mathsf{value}(q) = \mathbf{0}) \\
(ii) & \text{if} & (\nexists(s,q) \in T_E^v)(\mathsf{value}(q) = \mathbf{0}) \wedge \\
& & (\exists(s,q) \in T_E^v)(\mathsf{value}(q) = (a,b) \wedge a \ge \mathsf{h}(s)) \\
(iii) & \text{if} & (\nexists(s,q) \in T_E^v)(\mathsf{value}(q) = \mathbf{0}) \wedge \\
& & (\nexists(s,q) \in T_E^v)(\mathsf{value}(q) = (a,b) \wedge a \ge \mathsf{h}(s)) \wedge \\
& & (\exists(s,q) \in T_E^v)(\mathsf{value}(q) = (a,b) \wedge b \ge \mathsf{h}(s))
\end{cases}
\tag{6}
$$

General evaluation procedure of s is defined as follows:

$$eval(s) = \begin{cases} eval_\square(s) & \text{if} \quad \mathsf{last}(s) \in V_\square \\ eval_\Diamond(s) & \text{if} \quad \mathsf{last}(s) \in V_\Diamond \end{cases} \tag{7}$$

The sought strategy of $\Diamond$, π, then works in the following way.

$$\pi(p) = \begin{cases} q & \text{if} \quad (p,q) \in T_E^v \wedge eval(s) = (i) \wedge \mathsf{value}(q) = \mathbf{0} \\ q & \text{if} \quad (p,q) \in T_E^v \wedge eval(s) = (ii) \wedge \mathsf{value}(q) = (a,b) \wedge a \geq \mathsf{h}(s) \\ q & \text{if} \quad (p,q) \in T_E^v \wedge eval(s) = (iii) \wedge \mathsf{value}(q) = (a,b) \wedge b \geq \mathsf{h}(s) \end{cases} \tag{8}$$

Please note that for a node p such that $\mathsf{last}(p) \in V_\Diamond$ and $\mathsf{value}(p) = \mathbf{0}$, the existence of a successor with value $\mathbf{0}$ or value (a,b) such that $a \geq \mathsf{h}(s)$ or $b \geq \mathsf{h}(s)$ follows from the equations (3) and (4) and the fact that on the way from s to p, π decides based on s. If there is more than one successor with the appropriate value, for example, there are more successors with the value $\mathbf{0}$, any one of them can be selected π.

We note again that if a leaf q corresponding to a cycle is reached, then the play automatically continues at node $\mathsf{ph}(q)$. There is also a possibility that a leaf q not corresponding to a cycle is reached, which means that $\mathsf{last}(q) \in W_\Diamond$. In this case, by definition, $\Diamond$ has a strategy to send at least one of the counters towards $-\infty$. However, we would have to extend the strategy π to vertices from $W_\Diamond$ to deal with this case. For simplicity, knowing that such extension is possible, we stop the play at q and consider the play winning for $\Diamond$. If no leaf with last vertex in $W_\Diamond$ is reached, then the play stays in the tree ad infinitum. The following three lemmas prove that the strategy π has the desired properties.

Lemma 3.1. Let $\Gamma = (G = (V, E, w), V_\square, V_\Diamond)$ be a 2-dim VASS game. Let further $v \in W_\square$ be the starting vertex, $R \in \mathcal{R}$, let the root (v) of the tree T^v have the value $\mathbf{0}$, and let the strategy π be defined as in (8). Then, the strategy π ensures that exactly one of the following claims holds.

(I) A leaf r such that $\mathsf{last}(r) \in W_\Diamond$ is reached.

(II) Only bad cycles and cycles from $A_{=R} \cup B_{=R}$ are traversed, and a bad cycle is traversed infinitely many times.

(III) There is a point from which onwards all traversed cycles are from $A_{=R}$.

(IV) There is a point from which onwards all traversed cycles are from $B_{=R}$.

Proof: The claims (I)-(IV) are obviously mutually exclusive, and so we don't have to bother with the "exactly one" part of the claim of the lemma.

Let's first prove that it is impossible that a good cycle is traversed. This is easy because the root $(v) \in T_V^v$ has $\mathsf{value}((v)) = \mathbf{0}$. Strategy π always chooses a successor with value $\mathbf{0}$ or a two-component value. When it is $\square$'s call to choose a successor, he cannot choose a node with value $\mathbf{1}$, because it follows from (3) that no successor of a node p such that $\mathsf{last}(p) \in V_\square$ and $\mathsf{value}(p) = \mathbf{0}$ or $\mathsf{value}(p) = (a,b)$ can have value $\mathbf{1}$. Therefore, since traversing a good cycle corresponds to reaching a leaf with value $\mathbf{1}$, if $\Diamond$ uses π, then no good cycle can be traversed.

If a leaf r such that $\mathsf{last}(r) \in W_\Diamond$ is reached, or a leaf corresponding to a bad cycle is reached infinitely many times, then we are done. Otherwise, the play is infinite and there is a point from

which onwards only leaves corresponding to cycles from $A_{=R} \cup B_{=R}$ are reached. After the last bad cycle was traversed (or, at the beginning, if no bad cycle was traversed), we are at an inner node p such that $\mathsf{value}(p) = \mathbf{0}$ or $\mathsf{value}(p) = (a, b)$ such that $a \geq \mathsf{h}(\mathsf{deepestzero}(p))$ or $b \geq \mathsf{h}(\mathsf{deepestzero}(p))$. From p onwards, only leaves corresponding to cycles from $A_{=R} \cup B_{=R}$ are reached. We will prove that the play stays at levels greater or equal to $\mathsf{h}(\mathsf{deepestzero}(p))$, and only cycles from $A_{=R}$ or only cycles from $B_{=R}$ are traversed, until an inner node with value $\mathbf{0}$ at a deeper level than $\mathsf{h}(\mathsf{deepestzero}(p))$ is visited. This implies that $\square$ can alternate the cycles from $A_{=R}$ and $B_{=R}$ only finitely many times. So let's prove this claim.

Let $s = \mathsf{deepestzero}(p)$. If $eval(s) = (i)$, then π ensures that the successor of s has the value $\mathbf{0}$, and so it must be the case that $s = p$. Therefore, we will visit a node with value $\mathbf{0}$ at a deeper level in the next step, and so the claim holds. If $eval(s) = (ii)$ or $eval(s) = (iii)$, then let's suppose, without loss of generality, that $eval(s) = (ii)$. Let further $(s = p_0, \ldots, p_k)$ be the sequence of visited nodes from s to the first leaf, i.e., p_k is a leaf. The fact that $s = \mathsf{deepestzero}(p)$ implies, that there is $i \in \{0, \ldots, k - 1\}$ such that $p_i = p$ and for each $j \in \{1, \ldots, i\}$, p_j has a two-component value. If for some $j \in \{i + 1, \ldots, k - 1\}$, it holds that $\mathsf{value}(p_j) = \mathbf{0}$, we are done. Otherwise, let $(a_1, b_1), \ldots, (a_k, b_k)$ be the sequence of values of nodes $p_1, \ldots, p_k$. Please note that the leaf p_k has a two-component value, because we suppose that no bad cycles are traversed. The strategy π ensures that $a_1, \ldots, a_k \geq \mathsf{h}(s)$, and so $\mathsf{ce}(p_k) \in A_{=R}$, and $\mathsf{h}(\mathsf{ph}(p_k)) = a_k \geq \mathsf{h}(s)$. Therefore, only cycles from $A_{=R}$ are traversed until an inner node with value $\mathbf{0}$ at a deeper level than $\mathsf{h}(s)$ is visited. The claim is proved.

When an inner node p' such that $\mathsf{value}(p') = \mathbf{0}$ and $\mathsf{h}(p') > \mathsf{h}(s)$ is visited, we can repeat the arguments and prove that the play stays at level $\mathsf{h}(p')$ and deeper, and only cycles from $A_{=R}$ or only cycles from $B_{=R}$ are traversed, until an inner node with value $\mathbf{0}$ at a deeper level than $\mathsf{h}(p')$ is visited. The maximal depth of a node is $|V|$, and so there must be a point from which onwards only cycles from $A_{=R}$, or only cycles from $B_{=R}$ are traversed. Therefore, if claims (I) and (II) of the lemma are not satisfied, then one of the claims (III) and (IV) is. $\qquad\square$

Lemma 3.2. Let $a, b, a', b' \in \mathbb{Z}$; $|a|, |b|, |a'|, |b'| > 0$; $\frac{a}{b} < \frac{a'}{b'}$, and let b and b' have the same sign. Then $\frac{a}{b} < \frac{a+a'}{b+b'} < \frac{a'}{b'}$.

Proof: Since $\frac{a}{b} < \frac{a'}{b'}$, it holds that $ab' < a'b$. So, $(a + a')b = ab + a'b > ab + ab' = a(b + b')$. Therefore, $\frac{a}{b} < \frac{a+a'}{b+b'}$.

The second inequality is proved similarly: $(a + a')b' = ab' + a'b' < a'b + a'b' = a'(b + b')$. Therefore, $\frac{a+a'}{b+b'} < \frac{a'}{b'}$. $\qquad\square$

Lemma 3.3. Let $\Gamma = (G = (V, E, w), V_\square, V_\Diamond)$ be a 2-dim VASS game. Let further $v \in W_\square$ be the starting vertex, $R \in \mathcal{R}$, let the root (v) of the tree T^v have the value $\mathbf{0}$, and let the strategy π be defined as in (8). Let $\Diamond$ use the strategy π, let $\square$ use arbitrary strategy. The outcome of these two strategies corresponds to a sequence of nodes $(p_0, p_1, p_2, \ldots)$. Let $(r_0, r_1, r_2, \ldots)$ be the subsequence of the sequence containing all reached leaves, and let $K \in \mathbb{N}_0$. Then, either the sequence is finite, i.e., the last leaf r_k has $\mathsf{last}(r_k) \in W_\Diamond$, or the sequence is infinite and there is $k \in \mathbb{N}_0$ such that $\sum_{i=0}^{k-1} w_1(\mathsf{ce}(r_i)) < -K \vee \sum_{i=0}^{k-1} w_2(\mathsf{ce}(r_i)) < -K$.

Proof: To prove the lemma, we will use Lemma 3.1. If claim (I) of Lemma 3.1 holds, then we are done. If claim (III) of Lemma 3.1 holds, then there is $i \in N_0$ such that for each $j \geq i$, $\mathsf{ce}(r_j) \in A_{=R}$, and so the sum of the first weights increases and, more importantly, the sum of the second weights decreases. Therefore, the sum of the second weights will eventually go below $-K$, and so we are

done too. The case where the claim (IV) of Lemma 3.1 holds is symmetric. It remains to examine the case where the claim (II) of Lemma 3.1 holds.

Let $N_1 \subseteq N$ be the set of cycles c such that $w_1(c) = 0 \wedge w_2(c) < 0$.

Let $N_2 \subseteq N$ be the set of cycles c such that $w_1(c) < 0 \wedge w_2(c) = 0$.

Let $N_3 \subseteq N$ be the set of cycles c such that $w_1(c) < 0 \wedge w_2(c) < 0$.

Recall that the set $A_{>R} \subseteq A$ is the set of cycles c such that $w_1(c) > 0 \wedge w_2(c) < 0 \wedge \frac{w_1(c)}{w_2(c)} > R$.

Recall that the set $B_{<R} \subseteq B$ is the set of cycles c such that $w_1(c) < 0 \wedge w_2(c) > 0 \wedge \frac{w_1(c)}{w_2(c)} < R$.

Please note that $N_1 \cup N_2 \cup N_3 \cup A_{>R} \cup B_{<R}$ is the set of all possible bad cycles.

Let $(r_0, \ldots, r_k)$ be a prefix of $(r_0, r_1, r_2, \ldots)$ such that there are at least $15 \cdot |V|^5 \cdot K$ bad cycles in the prefix. Since a bad cycle is traversed infinitely many times, such prefix must exist. Now, let:

(a_1, b_1) be the sum of the weights of the bad cycles from N_1 in the prefix, and let n_1 be their number. In particular, $a_1 = 0$ and $b_1 < 0$.

(a_2, b_2) be the sum of the weights of the bad cycles from $A_{>R}$ in the prefix, and let n_2 be their number. In particular, $a_2 > 0$, $b_2 < 0$, and $\frac{a_2}{b_2} > R$.

(a_3, b_3) be the sum of the weights of the cycles from $A_{=R} \cup B_{=R}$ in the prefix. In particular, $a_3 > 0$ and $b_3 < 0$, or $a_3 < 0$ and $b_3 > 0$, and $\frac{a_3}{b_3} = R$.

(a_4, b_4) be the sum of the weights of the bad cycles from $B_{<R}$ in the prefix, and let n_4 be their number. In particular, $a_4 < 0$, $b_4 > 0$, and $\frac{a_4}{b_4} < R$.

(a_5, b_5) be the sum of the weights of the bad cycles from N_2 in the prefix, and let n_5 be their number. In particular, $a_5 < 0$ and $b_5 = 0$.

(a_6, b_6) be the sum of the weights of the bad cycles from N_3 in the prefix, and let n_6 be their number. In particular, $a_6 < 0$ and $b_6 < 0$.

Please note that $(a_1 + a_2 + a_3 + a_4 + a_5 + a_6, b_1 + b_2 + b_3 + b_4 + b_5 + b_6)$ is the sum of the weights of all the cycles in the prefix, and $n_1 + n_2 + n_4 + n_5 + n_6 \geq 15 \cdot |V|^5 \cdot K$. It follows, that at least one of the numbers n_1, n_2, n_4, n_5, n_6 is greater or equal to $3 \cdot |V|^5 \cdot K$. Let's consider two cases. Case 1: $n_6 \geq 3 \cdot |V|^5 \cdot K$. Case 2: $n_6 < 3 \cdot |V|^5 \cdot K$. Let's first look closer at case 1:

We will prove that if $a_1 + a_2 + a_3 + a_4 + a_5 \geq 0$, then $b_1 + b_2 + b_3 + b_4 + b_5 \leq 0$. Since there are at least $3 \cdot |V|^5 \cdot K$ cycles of type N_3, if $a_1 + a_2 + a_3 + a_4 + a_5 \leq 0 \vee b_1 + b_2 + b_3 + b_4 + b_5 \leq 0$, then $a_1 + a_2 + a_3 + a_4 + a_5 + a_6 < -K \vee b_1 + b_2 + b_3 + b_4 + b_5 + b_6 < -K$. Without loss of generality, let's suppose that $a_3 \geq 0$, and let $a = a_1 + a_2 + a_3$; $b = b_1 + b_2 + b_3$; $a' = a_4 + a_5$; $b' = b_4 + b_5$. (In case $a_3 < 0$, we would move a_3 and b_3 to a' and b'.) If $a = 0$, then since $a' \leq 0$, we are done. If $b' = 0$, then since $b \leq 0$, we are done too. So let's suppose that $a > 0$ and $b' > 0$. It follows that $b < 0$ and $a' < 0$. By Lemma 3.2, and the fact that cycles of type N_1 increase the ratio of cycles of type A and cycles of type N_2 decrease the ratio of cycles of type B, it holds that $\frac{a}{b} > \frac{a'}{b'}$, and so $ab' < a'b$. Therefore, if we develop the inequality $a + a' \geq 0$ into the inequality $ab + a'b \leq 0$, we can see that $ab + ab' < 0$, which can be developed into $b + b' < 0$ and we are done. This ends case 1. Let's now look at case 2, the case where $n_6 < 3 \cdot |V|^5 \cdot K$:

We will prove that if $a_1 + a_2 + a_3 + a_4 + a_5 + a_6 \geq -K$, then $b_1 + b_2 + b_3 + b_4 + b_5 + b_6 < -K$. Actually, we will prove a stronger claim: if $a_1 + a_2 + a_3 + a_4 + a_5 \geq -K$, then $b_1 + b_2 + b_3 + b_4 + b_5 < -K$. Without loss of generality, let's again suppose that $a_3 \geq 0$, and let $a = a_1 + a_2 + a_3$; $b = b_1 + b_2 + b_3$; $a' = a_4 + a_5$; $b' = b_4 + b_5$. Since $n_6 < 3 \cdot |V|^5 \cdot K$, it must hold that $b \leq -3 \cdot |V|^5 \cdot K \vee a' \leq -3 \cdot |V|^5 \cdot K$, because $n_1 + n_2 + n_4 + n_5 + n_6 \geq 15 \cdot |V|^5 \cdot K$. If $a = 0 \wedge b' = 0$, then we are done. Let's now examine the three remaining cases.

$a = 0 \wedge b' > 0$. It follows that $a' < 0$. By Lemma 3.2, and the fact that cycles of type N_2 decrease the overall ratio of cycles, and the fact that the greatest possible ratio is $-\frac{1}{|V|}$, it holds that $-\frac{1}{|V|} \geq \frac{a'}{b'}$, and so $-\frac{1}{|V|}b' \geq a'$. Therefore, if $a' = a + a' \geq -K$, then $-\frac{1}{|V|}b' \geq -K$, and so we can see that

$b' \leq K|V|$. The inequality $a' \geq -K$ also implies that $b \leq -3 \cdot |V|^5 \cdot K$, and so $b + b' < -K$ and we are done.

$a > 0 \wedge b' = 0$. It follows that $b < 0$. We will prove the implication $a + a' \geq -K \Rightarrow b + b' < -K$ by proving the equivalent implication $b + b' \geq -K \Rightarrow a + a' < -K$. By Lemma 3.2, and the fact that cycles of type N_1 increase the overall ratio of cycles, and the fact that the smallest possible ratio is $-|V|$, it holds that $-|V| \leq \frac{a}{b}$, and so $-\frac{1}{|V|}a \geq b$. Therefore, if $b = b + b' \geq -K$, then $-\frac{1}{|V|}a \geq -K$, and so we can see that $a \leq K|V|$. The inequality $b \geq -K$ also implies that $a' \leq -3 \cdot |V|^5 \cdot K$, and so $a + a' < -K$ and we are done.

$a > 0 \wedge b' > 0$. It follows that $b < 0$ and $a' < 0$. By Lemma 3.2, and the fact that cycles of type N_1 increase the overall ratio of cycles and cycles of type N_2 decrease the overall ratio of cycles, and the fact that two different ratios differ by more than $\frac{1}{|V|^2}$, it holds that $\frac{a}{b} > \frac{a'}{b'} + \frac{1}{|V|^2}$. It also holds that $\frac{a}{b} \geq -|V|$. Recall that $b \leq -3 \cdot |V|^5 \cdot K \vee a' \leq -3 \cdot |V|^5 \cdot K$, the assumption is that $a + a' \geq -K$, and we want to prove that $b + b' < -K$. First of all, we will show that $b \leq -2 \cdot |V|^4 \cdot K$.

If $b \leq -3 \cdot |V|^5 \cdot K$, then we are done. Otherwise, $a' \leq -3 \cdot |V|^5 \cdot K$. From $a + a' \geq -K$, we have that $a \geq -K - a'$. We also know that $\frac{a}{b} \geq -|V|$, and so $\frac{-K-a'}{b} \geq -|V|$, which can be developed into $b \leq \frac{K+a'}{|V|} \leq \frac{K-3\cdot|V|^5\cdot K}{|V|} \leq \frac{-2\cdot|V|^5\cdot K}{|V|} = -2 \cdot |V|^4 \cdot K$. Let's now prove that $b + b' < -K$. We consider two cases. The first case is that $\frac{a'}{b'} \geq -|V|^2$. The second case is that $\frac{a'}{b'} < -|V|^2$.

If $\frac{a'}{b'} \geq -|V|^2$, then $-\frac{b'}{a'} \geq \frac{1}{|V|^2}$. From $\frac{a}{b} > \frac{a'}{b'} + \frac{1}{|V|^2}$ and $a \geq -K - a'$, it follows that $\frac{-K-a'}{b} > \frac{a'}{b'} + \frac{1}{|V|^2}$. This can be developed into $b + b' < -\frac{b'}{a'} \cdot \left(K + \frac{1}{|V|^2} \cdot b \right) \leq \frac{1}{|V|^2} \cdot \left(K - \frac{1}{|V|^2} \cdot 2 \cdot |V|^4 \cdot K \right) \leq \frac{1}{|V|^2} \cdot (-|V|^2 \cdot K) \leq -K$. It remains to consider the case where $\frac{a'}{b'} < -|V|^2$.

Let $\frac{a'}{b'} < -|V|^2$. We know that $\frac{-K-a'}{b} \geq \frac{a}{b} \geq -|V|$. This can be developed into $a' \geq |V| \cdot b - K$. Therefore, $-|V|^2 > \frac{a'}{b'} \geq \frac{|V|\cdot b - K}{b'}$. This can be developed into $K > |V| \cdot b + |V|^2 \cdot b'$, which in turn can be developed into $K + (|V|^2 - |V|) \cdot b > |V|^2 \cdot b + |V|^2 \cdot b'$. It follows that $b + b' < \frac{K+(|V|^2-|V|)\cdot b}{|V|^2} \leq \frac{K+(|V|^2-|V|)\cdot(-2\cdot|V|^4\cdot K)}{|V|^2} \leq \frac{K+|V|\cdot(-2\cdot|V|^4\cdot K)}{|V|^2} \leq \frac{-|V|^5\cdot K}{|V|^2} = -|V|^3 \cdot K \leq -K$. In the above, we have used that $|V| > 1$.

We have proved that if the claim (II) of Lemma 3.1 holds, then at least one of the sums goes below $-K$ where K is an arbitrary non-negative integer. $\qquad\square$

We have proved that there are only two possibilities for the value of the root: $\mathbf{1}$ and $(-1, -1)$. Let's now define the strategy for $\square$ that ensures that only cycles from $A_{\leq R} \cup B_{\geq R} \cup P$ are traversed, and the cycles from $A_{=R}$ and $B_{=R}$ are kept in balance.

3.4. The Local Strategy for $\square$

We will start with some intuition. The intuitive meaning of the node value $\mathbf{1}$ is that $\square$ has a strategy to reach a leaf corresponding to a good cycle. The meaning of the node value (a, b) is more complex.

If a node p has the value (a, b), then $\square$ has a strategy to reach a leaf corresponding to a good cycle or a cycle from $A_{=R} \cup B_{=R}$. Moreover, the strategy can be chosen in such a way that if the reached leaf q has $\mathsf{ce}(q) \in A_{=R}$, then $\mathsf{rh}(q) \leq a$, or the strategy can be chosen in such a way that if the reached leaf q has $\mathsf{ce}(q) \in B_{=R}$, then $\mathsf{rh}(q) \leq b$. In particular, if $a = -1$, then $\square$ can force a good cycle or a cycle from $B_{=R}$, and if $b = -1$, then $\square$ can force a good cycle or a cycle from $A_{=R}$. The rules for assigning values to nodes stipulate that $a < \mathsf{h}(p)$ and $b < \mathsf{h}(p)$. This is important for balancing the cycles from $A_{=R}$ and $B_{=R}$.

The player $\square$ may not be able to alternate the cycles from $A_{=R}$ and $B_{=R}$ arbitrarily, as Figure 2 shows. In Figure 2 (a), a 2-dim VASS game is depicted. Squares are $\square$'s vertices and the diamond is
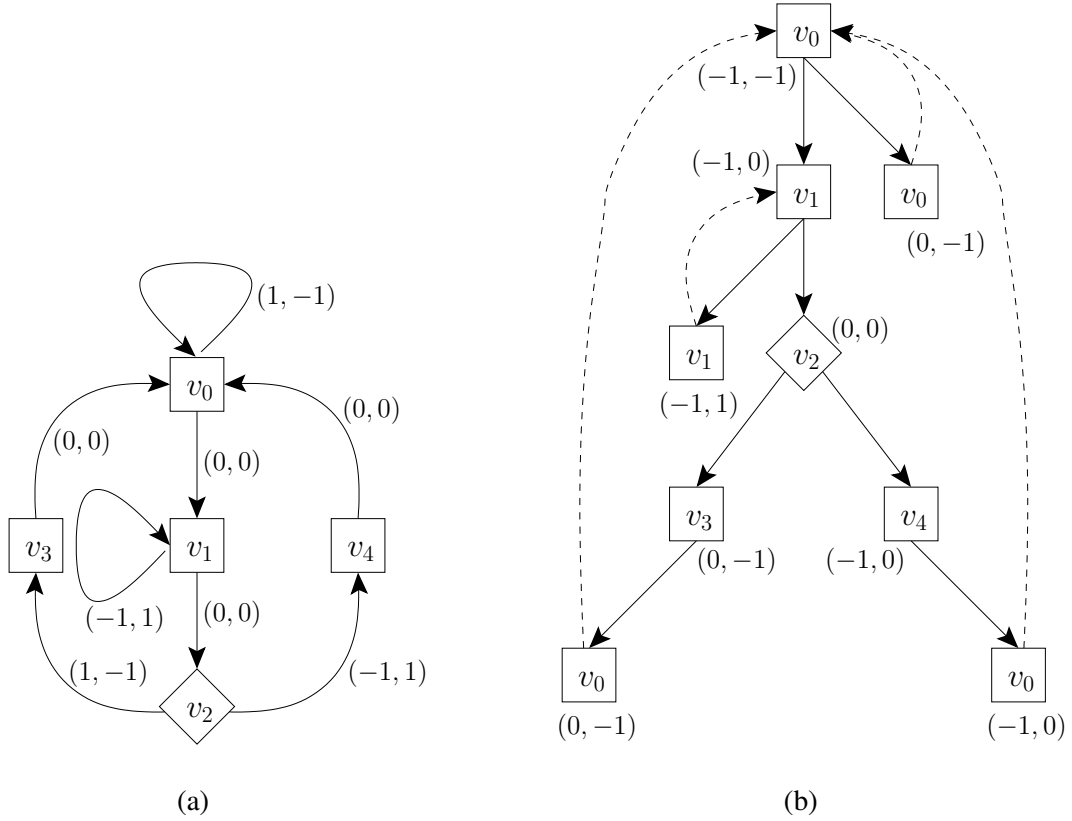

Figure 2.   Example tree valuation: (a) example game, (b) tree T^{v_0}

a $\diamond$'s vertex. The pairs of numbers are weights of the edges depicted as arrows. In this game, $\square$ can win from all vertices. Let $R = -1$, then all cycles in the figure are from $A_{=R} \cup B_{=R}$. In Figure 2 (b), the tree T^{v_0} is shown. The pairs of numbers are values of the nodes and the dashed arrows emanating from leaves show, for each leaf, where the game (projected on the tree) continues when it reaches the leaf.

If the play starts from v_0, then at the beginning, $\square$ is able to traverse a cycle from $A_{=R}$ arbitrary number of times (the cycle (v_0, v_0)), after that he is able to traverse a cycle from $B_{=R}$ arbitrary number of times (the cycle (v_1, v_1)). However, after that he is not able to start traversing cycles from $A_{=R}$ immediately. The value of the node $(v_0, v_1) \in T_V^{v_0}$ at depth 1 is $(-1, 0)$, which indicates that $\square$ is able to force a cycle from $B_{=R}$, but not from $A_{=R}$. However, $\square$ has a strategy that ensures that if $\diamond$ forces a cycle from $B_{=R}$, then the play returns to a node at smaller depth, namely, the depth 0. At the depth 0, $\square$ is, again, able to force a cycle from $A_{=R}$.

In general, we claim that $\square$ has a strategy that ensures that only good cycles and cycles from $A_{=R} \cup B_{=R}$ are traversed. Moreover, the strategy also ensures that both the sum of the first weights of the cycles from $A_{=R} \cup B_{=R}$ and the sum of the second weights of the cycles from $A_{=R} \cup B_{=R}$ is always greater or equal to $-2 \cdot |V|^2$.

In the case where $\mathsf{value}((v)) = \mathbf{1}$, $\square$ has a strategy to traverse only good cycles and the claim obviously holds.

The second case is that $\mathsf{value}((v)) = (-1, -1)$. In this case, $\square$ has a strategy that ensures that only nodes p with value $\mathbf{1}$ or value $(a, b) \in \{-1, \dots, |V|\}^2$ are visited. This alone implies that only good cycles and cycles from $A_{=R} \cup B_{=R}$ are traversed. Moreover, he is able to choose the strategy

in such a way that it balances the cycles from $A_{=R}$ and $B_{=R}$. When an imbalance between the cycles from $A_{=R}$ and $B_{=R}$ occurs, let's say that too many cycles from $A_{=R}$ have been traversed, then $\square$ aims to traverse cycles from $B_{=R}$ or good cycles. If the current node p has the value $\mathbf{1}$, then $\square$ can ensure that the next traversed cycle is a good cycle, which does not worsen the imbalance. If p has the value (a, b) and $a \neq -1$, $\Diamond$ can force a cycle from $A_{=R}$, but if she does, $\square$ can ensure that the play returns to the depth a or smaller, and since $a < \mathsf{h}(p)$, we return to a smaller depth than the depth of p. We can continue using the same reasoning and conclude that after traversing at most $|V| - 1$ (maximal depth of an inner tree node) "unwanted" cycles from $A_{=R}$, we get to the root, where $\square$ can force cycles from $B_{=R}$ or good cycles. Therefore, he can alleviate the imbalance caused by the cycles from $A_{=R}$. Of course, the case when an imbalance is caused by cycles from $B_{=R}$ is symmetric. Formal definition of this "balancing" strategy of $\square$ is as follows.

A general strategy of $\square$ is a function $\sigma : V^* \cdot V_\square \to V$, i.e., it decides based on the whole history of the play. However, the strategy we define now will decide based only on the current node of the tree T^v (which consists of fragments of the whole history) and some additional memory which could be computed from the complete history of the play.

Apart from the current node, $\square$ keeps a triple $(x, y, z) \in \{-2 \cdot |V|^2, \ldots, 0, \ldots, 2 \cdot |V|^2\}^2 \times \{0, 1\}$, where x is the sum of the first weights of the traversed cycles from $A_{=R} \cup B_{=R}$, y is the sum of the second weights of the traversed cycles from $A_{=R} \cup B_{=R}$, and z is the mode of the strategy: $z = 0$ means that the strategy aims to traverse cycles from $A_{=R}$, and $z = 1$ means that the strategy aims to traverse cycles from $B_{=R}$. The memory plays a crucial role in keeping the traversed cycles from $A_{=R}$ and $B_{=R}$ in balance.

The strategy of $\square$ visits only nodes p of the tree T^v with $\mathsf{value}(p) = \mathbf{1}$ or $\mathsf{value}(p) = (a, b)$ (recall that $a, b < \mathsf{h}(p)$). The play starts at the root (v). It holds that $\mathsf{h}((v)) = 0$, and $\mathsf{value}((v)) = \mathbf{1}$ or $\mathsf{value}((v)) = (-1, -1)$. Initial state of the memory is $(0, 0, 0)$. Let's consider a general situation where we are at the inner node p such that $\mathsf{last}(p) \in V_\square$, $\mathsf{value}(p) = \mathbf{1}$ or $\mathsf{value}(p) = (a, b)$ such that $a, b < \mathsf{h}(p)$, and the current state of memory is (x, y, z), then the strategy of $\square$, denoted by σ, works as follows. Please note that the strategy does not have to consider leaves, because at each leaf q, the play automatically returns to the inner node $\mathsf{ph}(q)$. We define first, how a successor is chosen:

$$\sigma(p, (x, y, z)) = \begin{cases} q & \text{if} \quad (p, q) \in T_E^v \wedge \mathsf{value}(p) = \mathbf{1} \wedge \mathsf{value}(q) = \mathbf{1} \\ q & \text{if} \quad (p, q) \in T_E^v \wedge \mathsf{value}(p) = (a, b) \wedge z = 0 \wedge \mathsf{value}(q) = (a', b) \\ q & \text{if} \quad (p, q) \in T_E^v \wedge \mathsf{value}(p) = (a, b) \wedge z = 1 \wedge \mathsf{value}(q) = (a, b') \end{cases} \quad (9)$$

Please note that for a node p with $\mathsf{value}(p) = (a, b)$, the existence of a successor with value (a', b) and the existence of a successor with value (a, b') follows from (3). It is also possible that these are not two distinct successors but only one with value (a, b).

We define now, how the memory is updated. The memory is updated only when a leaf is reached, so let's suppose that we have reached the leaf q. Then the memory (x, y, z) is updated to:

$$
\begin{aligned}
&(x, y, z) &&\text{if} \quad \mathsf{ce}(q) \text{ is a good cycle} \\
&(x + w_1(\mathsf{ce}(q)), y + w_2(\mathsf{ce}(q)), z) &&\text{if} \quad \mathsf{ce}(q) \in A_{=R} \cup B_{=R} \wedge \\
& && \qquad z = 0 \wedge \\
& && \qquad (\ x + w_1(\mathsf{ce}(q)) < 0 \vee \\
& && \qquad \quad (\ x + w_1(\mathsf{ce}(q)) \in [-|V|^2, |V|^2] \wedge \\
& && \qquad \qquad y + w_2(\mathsf{ce}(q)) \in [-|V|^2, |V|^2] \ ) \ )
\end{aligned}
$$

$$
\begin{array}{ll}
(x + w_1(\mathsf{ce}(q)), y + w_2(\mathsf{ce}(q)), z) & \text{if} \quad \mathsf{ce}(q) \in A_{=R} \cup B_{=R} \, \wedge \\
& \qquad z = 1 \, \wedge \\
& \qquad (\ y + w_2(\mathsf{ce}(q)) < 0 \, \vee \\
& \qquad \quad (\ x + w_1(\mathsf{ce}(q)) \in [-|V|^2, |V|^2] \, \wedge \\
& \qquad \qquad y + w_2(\mathsf{ce}(q)) \in [-|V|^2, |V|^2]\ )\ ) \\[4pt]
(x + w_1(\mathsf{ce}(q)), y + w_2(\mathsf{ce}(q)), 1) & \text{if} \quad \mathsf{ce}(q) \in A_{=R} \cup B_{=R} \, \wedge \\
& \qquad z = 0 \, \wedge \\
& \qquad x + w_1(\mathsf{ce}(q)) \geq 0 \, \wedge \qquad\qquad (10)\\
& \qquad (\ |x + w_1(\mathsf{ce}(q))| > |V|^2 \, \vee \\
& \qquad \quad |y + w_2(\mathsf{ce}(q))| > |V|^2\ ) \\[4pt]
(x + w_1(\mathsf{ce}(q)), y + w_2(\mathsf{ce}(q)), 0) & \text{if} \quad \mathsf{ce}(q) \in A_{=R} \cup B_{=R} \, \wedge \\
& \qquad z = 1 \, \wedge \\
& \qquad y + w_2(\mathsf{ce}(q)) \geq 0 \, \wedge \\
& \qquad (\ |x + w_1(\mathsf{ce}(q))| > |V|^2 \, \vee \\
& \qquad \quad |y + w_2(\mathsf{ce}(q))| > |V|^2\ )
\end{array}
$$

We note again that if a leaf q is reached, then the play automatically continues at node $\mathsf{ph}(q)$, and so the play is infinite. Let's now take a closer look at the memory updates.

While $x, y \in [-|V|^2, |V|^2]$, the strategy does not change the type of cycles it aims for, z is not changed (first 3 items in (10)). When $|x|$ or $|y|$ exceeds $|V|^2$, $z = 0$, and $x \geq 0$, it means that too many cycles from $A_{=R}$ have been traversed. Therefore z is changed to 1, and so the strategy aims for cycles from $B_{=R}$ (4th item in (10)). As described before, even after this action, some cycles from $A_{=R}$ may be traversed before cycles from $B_{=R}$, but there can be at most $|V| - 1$ of these unwanted cycles, therefore x and y do not leave the interval $[-2 \cdot |V|^2, 2 \cdot |V|^2]$. The situation where too many cycles from $B_{=R}$ have been traversed is dealt with analogously (5th item in (10)).

The following two lemmas show that the strategy σ satisfies the desired properties. An intuition why they hold was given above.

Lemma 3.4. Let $\Gamma = (G = (V, E, w), V_\square, V_\lozenge)$ be a 2-dim VASS game. Let further $v \in W_\square$ be the starting vertex, $R \in \mathcal{R}$, and let the strategy σ be defined as in (9). Then the following holds. If the value of the root (v) of the tree T^v is $\mathsf{value}((v)) = \mathbf{1}$, then the strategy σ ensures that only nodes p with $\mathsf{value}(p) = \mathbf{1}$ are visited. If the value of the root (v) of the tree T^v is $\mathsf{value}((v)) = (-1, -1)$, then the strategy σ ensures that only nodes p with $\mathsf{value}(p) = \mathbf{1}$ or $\mathsf{value}(p) = (a, b)$ such that $a, b < \mathsf{h}(p)$ are visited.

Proof: We will show the lemma by showing that it holds for all prefixes of the infinite play, and we will show it by induction on the length of the prefixes. We will prove only the more complicated case where $\mathsf{value}((v)) = (-1, -1)$, the case where $\mathsf{value}((v)) = \mathbf{1}$ can be proved similarly.

We consider the play as a sequence of nodes of the tree T^v. For $k = 0$ the claim obviously holds because the play starts from the root (v) and $\mathsf{value}((v)) = (-1, -1)$. It remains to show that if the claim holds for a prefix of length k, then it also holds for a prefix of length $k + 1$.

Let's denote the prefix of length k by $(p_0, \ldots, p_k)$, where $p_0, \ldots, p_k$ is the sequence of visited nodes. Let's first suppose that p_k is not a leaf and consider two cases: $\mathsf{last}(p_k) \in V_\square$ and $\mathsf{last}(p_k) \in V_\lozenge$.

last(p_k) $\in V_\square$. If value(p_k) = **1**, then by (9), the next node p_{k+1} has value(p_{k+1}) = **1** and the claim holds. If value(p_k) = (a, b), then also by (9), the next node p_{k+1} has value(p_{k+1}) = (a', b) or value(p_{k+1}) = (a, b') such that $a, b, a', b' <$ h(p_{k+1}). The last inequality follows from the fact that h(p_{k+1}) = h(p_k) + 1 and the fact that by (3) and (4) it is impossible for a node with a two-component value to have one component of the value greater or equal to its depth.

last(p_k) $\in V_\Diamond$. If value(p_k) = **1**, then by (4), there are only successors with value equal to **1**, and so the claim holds. If value(p_k) = (a, b), then also by (4), there are only successors with value equal to **1** or a two-component value with the first component less or equal to a and the second component less or equal to b. Since a successor of p_k is one level deeper than p_k, the claim holds.

It remains to consider the case where p_k is a leaf. In this case the play automatically returns to the node ph(p_k). This node has already been visited, and so the claim holds for it.   □

Lemma 3.4 implies that only good cycles and cycles from $A_{=R} \cup B_{=R}$ are traversed. The next lemma states that the cycles from $A_{=R}$ and $B_{=R}$ are kept in balance.

Lemma 3.5. Let $\Gamma = (G = (V, E, w), V_\square, V_\Diamond)$ be a 2-dim VASS game. Let further $v \in W_\square$ be the starting vertex, $R \in \mathcal{R}$, let the root (v) of the tree T^v have the value **1** or $(-1, -1)$, and let the strategy σ be defined as in (9). Let $\square$ use the strategy σ, let $\Diamond$ use an arbitrary strategy. The outcome of these two strategies corresponds to a sequence of nodes $(p_0, p_1, p_2, \dots)$. Let $(q_0, q_1, q_2, \dots)$ be the subsequence of the sequence containing *all* reached leaves corresponding to cycles from $A_{=R} \cup B_{=R}$. In particular, for each $i \in \mathbb{N}_0$, ce(q_i) $\in A_{=R} \cup B_{=R}$. Then for each $k \in \mathbb{N}_0$, it holds that $\sum_{i=0}^{k} w_j($ce(q_i))$| \leq 2 \cdot |V|^2$ where $j = 0, 1$.

Proof: We note that if from some point onwards, cycles from $A_{=R} \cup B_{=R}$ are not traversed, then the sequence $(q_0, q_1, q_2, \dots)$ is finite. Then $k \in \mathbb{N}_0$ in the claim of the lemma should be changed to $k \in \{0, \dots, k_{\max} - 1\}$ where $k_{\max}$ is the number of elements of the sequence. The proof applies also to the finite case.

The play starts from the root $(v) \in T_V$ and the initial state of the memory of $\square$ is $(0, 0, 0)$. The third component of the memory being 0 indicates that the strategy aims to reach leaves corresponding to cycles from $A_{=R}$. Let's consider two cases. First case is that value((v)) = **1**. By Lemma 3.4, in this case, $\square$ has a strategy to reach only leaves corresponding to good cycles, so the claim of the lemma obviously holds. The second case is that value((v)) = $(-1, -1)$. In the following, we will use (x, y, z) to refer to the current state of $\square$'s memory.

In the case of the root having the value $(-1, -1)$, while $z = 0$, σ ensures that only nodes p with value(p) = $(a, -1)$ or value(p) = **1** are reached where $a \in \{-1, 0, \dots, |V|\}$, which means that only leaves corresponding to good cycles or cycles from $A_{=R}$ are reached. The sum of the first weights of the traversed cycles from $A_{=R}$ is stored in x and the sum of the second weights of the traversed cycles from $A_{=R}$ is stored in y. When the absolute value of either of the sums exceeds $|V|^2$, z is set to 1 and σ now aims to reach leaves corresponding to cycles from $B_{=R}$. In this situation, the play just reached a leaf r and continues at node $p =$ ph(r) with value(p) = (a, b) such that $a, b <$ h(p). It follows from Lemma 3.4 and the fact that update to z takes place only when a leaf corresponding to a cycle from $A_{=R} \cup B_{=R}$ is reached.

While $z = 1$, σ ensures the following property. Let

$$(a_0^0, b_0^0), \dots, (a_{k_0-1}^0, b_{k_0-1}^0), (a_0^1, b_0^1), \dots, (a_{k_1-1}^1, b_{k_1-1}^1), \dots$$

be the sequence of values of all visited nodes having two-component value, and let

$$p_0^0, \dots, p_{k_0-1}^0, p_0^1, \dots, p_{k_1-1}^1, \dots$$

be the corresponding sequence of visited nodes. In Figure 3 is an example of such a sequence. Squares are nodes with the last vertex from $V_\square$ and diamonds are nodes with the last vertex from $V_\lozenge$. Filled nodes are leaves. The upper index indicates how many leaves have been reached since z was set to 1. The leaf-visit that caused that z was set to 1 is not counted. So, for $i = 0$, the sequence $p_0^i, \ldots, p_{k_i-1}^i$ is the sequence of the nodes with two-component values which have been visited since the beginning (the moment when z was set to 1) until the first leaf-visit, and for $i > 0$, the sequence $p_0^i, \ldots, p_{k_i-1}^i$ is the sequence of the nodes with two-component values visited after the i-th and until the $(i + 1)$-th leaf-visit. For $i > 0$, it is possible that $k_i = 0$, which indicates that no node with two-component value was reached between the i-th and the $(i + 1)$-th leaf-visit. In Figure 3, $k_2 = 0$. Please note that σ ensures that if a node with value $\mathbf{1}$ is reached, then until a leaf is visited, all subsequent nodes have value $\mathbf{1}$ (including the leaf).

Figure 3.   Example node sequence

For each $i \in \mathbb{N}_0$, it holds that $a_0^i \geq \cdots \geq a_{k_i-1}^i$. This is ensured by the strategy σ: for nodes p with $\mathsf{last}(p) \in V_\square$, σ selects a successor node with the same first component of the value, and for nodes p with $\mathsf{last}(p) \in V_\lozenge$, there are only successors with smaller or equal first component of the value or the value $\mathbf{1}$. Let's now examine the relation of values with different upper index, i.e., values of nodes preceding different leaf-visits. We will prove the following claim.

(i) For each $i \in \mathbb{N}_0$, if $k_{i+1} > 0$, then $a_0^{i+1} < \mathsf{h}(p_0^j)$ where j is the greatest number less or equal to i such that $k_{j-1} > 0$ and $p_{k_{j-1}-1}^{j-1}$ is a leaf such that $\mathsf{ce}(p_{k_{j-1}-1}^{j-1}) \in A_{=R}$. If no such number exists, then $j = 0$. Moreover, if $k_i > 0$ and $p_{k_i-1}^i$ is a leaf such that $\mathsf{ce}(p_{k_i-1}^i) \in A_{=R}$, then $\mathsf{h}(p_0^{i+1}) < \mathsf{h}(p_0^j)$.

To prove (i), let $i \in \mathbb{N}_0$ such that $k_{i+1} > 0$, let j be as defined in (i) and consider the sequence $r_j, \ldots, r_i$ of leaves reached between p_0^j and p_0^{i+1}. Please note that we use the fact that $k_j > 0$, which will be proved later. Then, for each $d \in \{j, \ldots, i - 1\}$, it holds that $\mathsf{ce}(r_d)$ is either a good cycle or a cycle from $B_{=R}$. The cycle $\mathsf{ce}(r_i)$ is a good cycle or a cycle from $A_{=R} \cup B_{=R}$. Let's first consider the case where $\mathsf{ce}(r_i)$ is either a good cycle or a cycle from $B_{=R}$. We will show by induction on $d = j, \ldots, i + 1$ that for each $f \in \{j, \ldots, d\}$, it holds that either $k_f = 0$ or $a_0^f < \mathsf{h}(p_0^j)$.

$d = j$. From the fact that either $j = 0$ or $k_{j-1} > 0$ and $p_{k_{j-1}-1}^{j-1}$ is a leaf such that $\mathsf{ce}(p_{k_{j-1}-1}^{j-1}) \in A_{=R}$, it follows that $k_d > 0$, and $a_0^d < \mathsf{h}(p_0^j)$ follows from Lemma 3.4. This completes the induction base. The induction step follows.

$j < d \leq i + 1$. If $k_d = 0$, then we are done. If $k_d > 0$, then we consider two cases. First, $\mathsf{h}(p_0^d) < \mathsf{h}(p_0^j)$. By Lemma 3.4, $a_0^d < \mathsf{h}(p_0^d)$, and so $a_0^d < \mathsf{h}(p_0^j)$. Second, $\mathsf{h}(p_0^d) \geq \mathsf{h}(p_0^j)$, then $p_0^d = p_g^f$ where $f \in \{j, \ldots, d-1\}$ such that $k_f > 0$ and $g \in \{0, \ldots, k_f - 1\}$. By induction hypothesis, $a_0^f < \mathsf{h}(p_0^j)$. By properties of σ, $a_0^f \geq a_g^f$. Together, we have $\mathsf{h}(p_0^j) > a_0^f \geq a_g^f = a_0^d$. This completes the induction step.

To complete the proof of (i) it remains to consider the case where $\mathsf{ce}(r_i) \in A_{=R}$. If $\mathsf{ce}(r_i) \in A_{=R}$, then $k_{i+1} > 0$, $k_i > 0$, and $\mathsf{h}(p_0^{i+1}) = a_{k_i-1}^i \leq a_0^i$. From the proof by induction above, it follows that $a_0^i < \mathsf{h}(p_0^j)$, and so $\mathsf{h}(p_0^{i+1}) < \mathsf{h}(p_0^j)$. The claim (i) is proved.

Given the claim (i) it is now easy to prove the claim of the lemma. From (i), it follows that if a leaf r such that $\mathsf{ce}(r) \in A_{=R}$ is visited, then $\mathsf{h}(\mathsf{ph}(r)) < \mathsf{h}(p)$, where $p = \mathsf{ph}(r')$ where r' is the

previous leaf such that $\mathsf{ce}(r') \in A_{=R}$, visited after z was set to 1, or if no other cycle from $A_{=R}$ than $\mathsf{ce}(r)$ was traversed, then $p = p_0^0$. Therefore, while $z = 1$, a cycle from $A_{=R}$ can be traversed at most $(|V| - 1)$-times, because after at most $(|V| - 1)$-th traversal of a cycle from $A_{=R}$, we return to the root, which has the value $(-1, -1)$, and so σ ensures that only good cycles and cycles from $B_{=R}$ are traversed. Just after z was set to 1, $y \geq -|V|^2 - |V|$, and so after a cycle from $A_{=R}$ is traversed $(|V| - 1)$-times, it holds that $y \geq -2 \cdot |V|^2$. Traversing cycles from $B_{=R}$ then increases y and decreases x. Recall that the cycles from $A_{=R}$ and $B_{=R}$ have the same ratio of first and second weight, which implies that $x > 0$ if and only if $y < 0$, and $x < 0$ if and only if $y > 0$. Therefore, even if x goes below $-|V|^2$ before y gets to $|V|^2$, it holds that $y \geq 0$, and so z is set to 0 and we can repeat the arguments we used for the situation after z was set to 1. Together, we have that $[-2 \cdot |V|^2, 2 \cdot |V|^2]$ is a sufficient interval for x and y. The lemma is proved.   □

We have proved that for each $v \in W_\square$ and $R \in \mathcal{R}$, there is a strategy for $\square$ that ensures that if the play starts from v, then only cycles from $A_{<R} \cup B_{>R} \cup P$ are traversed, and the cycles from $A_{=R}$ and $B_{=R}$ are kept in balance. In the next section, we will define the global winning strategy for $\square$. The strategy will not only be winning, it will also ensure that both counters do not drop below their initial values by more than a constant that is of polynomial size with respect to $|V|$.

3.5.   The Global Strategy for $\square$

For technical convenience, let's number the elements of the set of the cycle ratios, namely, let $\mathcal{R} = \{R_1, \ldots, R_{|\mathcal{R}|}\}$ where $R_1 < \cdots < R_{|\mathcal{R}|}$. It holds that $|\mathcal{R}| \leq |V|^2$. By Lemma 3.5, for each $v \in W_\square$ and R_k such that $k \in \{1, \ldots, |\mathcal{R}|\}$, the player $\square$ has the strategy σ_k^v that ensures that only cycles from $P \cup A_{\leq R_k} \cup B_{\geq R_k}$ are traversed. Moreover, the cycles from $A_{=R_k}$ and $B_{=R_k}$ are balanced in the sense that the absolute value of both components of the sum of their weights never exceeds $2 \cdot |V|^2$. Also, when using the strategy σ_k^v, the play never leaves the set $W_\square$.

Using the above facts, we will now assemble a global strategy σ of $\square$ such that there is a constant $K \in \mathbb{N}_0$ of polynomial size with respect to $|V|$ such that whatever strategy π the opponent $\Diamond$ uses, the resulting infinite play $\mathsf{outcome}^\Gamma(v_0, \sigma, \pi) = (v_0, v_1, v_2, \ldots)$ satisfies the following. For each $k \in \mathbb{N}_0$, $\sum_{i=0}^{k-1} w_1(v_i, v_{i+1}) \geq -K$ and $\sum_{i=0}^{k-1} w_2(v_i, v_{i+1}) \geq -K$. The strategy σ will be assembled from the strategies σ_k^v where $v \in W_\square$ and $k \in \{1, \ldots, |\mathcal{R}|\}$. So, let's describe how this is done.

Each strategy σ_k^v has the three-component memory as described before. Let now $k \in \{1, \ldots, |\mathcal{R}|\}$. For each $v \in W_\square$, the strategy σ_k^v balances the cycles from $A_{=R_k}$ and $B_{=R_k}$. We will let all the strategies with the same k use the same three-component memory. Therefore, the global strategy σ will have $|\mathcal{R}|$ three-component memories, one for each k. For a specific $k \in \{1, \ldots, |\mathcal{R}|\}$, the three-component memory will be denoted by (x_k, y_k, z_k). Apart from that, σ will have additional memory that consists of two $|\mathcal{R}|$-tuples. The first $|\mathcal{R}|$-tuple will be $(a_1, \ldots, a_{|\mathcal{R}|}) \in \{0, \ldots, 4 \cdot |V|^4 + 3 \cdot |V|\}^{|\mathcal{R}|}$ and it will store the sums of the first weights of the traversed cycles from A, separately for each ratio. The second $|\mathcal{R}|$-tuple will be $(a'_1, \ldots, a'_{|\mathcal{R}|}) \in \{-4 \cdot |V|^4 - |V|, \ldots, 0\}^{|\mathcal{R}|}$ and it will store the sums of the first weights of the traversed cycles from B, separately for each ratio. However, when using the strategy σ_k^v, only traversed cycles from A and B with ratios R_i such that $i \neq k$ will be recorded in the additional memory. The traversed cycles with the ratio R_k will be recorded only in the three-component memory (x_k, y_k, z_k). The global strategy σ will also remember which strategy σ_k^v it is currently using by remembering the vertex v and the integer k. The strategy σ is defined as follows.

We will not describe (again) how the three-component memories are used and updated, we will only describe how the two additional $|\mathcal{R}|$-tuples are handled. The current tree that the strategy is working with is denoted by $T^v = (T_V^v, T_E^v)$ where (v) is the root of the tree. Let $v, k, (a_1, \ldots, a_{|\mathcal{R}|})$,

$(a'_1, \ldots, a'_{|\mathcal{R}|})$ be the current state of the additional memory, and let p be the current inner node in the current tree T^v. We will first describe how the strategy decides and then how the memory is updated. The strategy decides as follows:

$$\sigma(p, v, k, (a_1, \ldots, a_{|\mathcal{R}|}), (a'_1, \ldots, a'_{|\mathcal{R}|})) = \sigma^v_k(p) \tag{11}$$

Now, let us describe how the memory is updated. The initial state of the memory is $(v, 1, (0, \ldots, 0), (0, \ldots, 0))$ where v is the vertex the play starts from, and so the first tree the strategy σ works with is the tree T^v rooted at v, and the first used sub-strategy is σ^v_1. The two $|\mathcal{R}|$-tuples in the memory play a crucial role in keeping the traversed cycles from A and B in balance. As was already mentioned, the first $|\mathcal{R}|$-tuple records the sums of the first weights of the traversed cycles from A. There are two bounds that bound the elements of the tuple from above: a soft bound and a hard bound. The soft bound is equal to $4 \cdot |V|^4 + 2 \cdot |V|$ and we denote it by C_A. If some element a_i exceeds the soft bound, then the strategy takes some actions so that a_i is not increased further and it never exceeds the hard bound $\bar{C}_A$ which is equal to $4 \cdot |V|^4 + 3 \cdot |V|$. Similarly, there is a soft bound and a hard bound for the second $|\mathcal{R}|$-tuple. The second $|\mathcal{R}|$-tuple records the sums of the first weights of the traversed cycles from B. Unlike for the first tuple, the bounds for the second tuple bound the elements of the tuple from below. The soft bound is $C_B = -4 \cdot |V|^4$, and the hard bound is $\bar{C}_B = -4 \cdot |V|^4 - |V|$. Before explaining the actions the strategy takes to ensure that the hard bounds are never exceeded, we describe precisely how the memory is updated. It is updated only when a leaf in the current tree is reached, so let's suppose that we have reached the leaf q. Then the memory $(v, k, (a_1, \ldots, a_{|\mathcal{R}|}), (a'_1, \ldots, a'_{|\mathcal{R}|}))$ is updated to:

$$
\begin{array}{lll}
(v, k, \; (a_1, \ldots, a_{|\mathcal{R}|}), & \text{if} & \mathsf{ce}(q) \in P \cup A_{=R_k} \cup B_{=R_k} \\
\qquad (a'_1, \ldots, a'_{|\mathcal{R}|})) & & \\[4pt]
(v, k, \; (a_1, \ldots, a_i + w_1(\mathsf{ce}(q)), \ldots, a_{|\mathcal{R}|}), & \text{if} & \mathsf{ce}(q) \in A_{=R_i} \, \wedge \\
\qquad (a'_1, \ldots, a'_{|\mathcal{R}|})) & & i < k \, \wedge \\
& & a_i + w_1(\mathsf{ce}(q)) \le C_A \\[4pt]
(v, k, \; (a_1, \ldots, a_{|\mathcal{R}|}), & \text{if} & \mathsf{ce}(q) \in B_{=R_j} \, \wedge \\
\qquad (a'_1, \ldots, a'_j + w_1(\mathsf{ce}(q)), \ldots, a'_{|\mathcal{R}|})) & & j > k \, \wedge \\
& & a'_j + w_1(\mathsf{ce}(q)) \ge C_B \\[4pt]
(v, k, \; (a_1, \ldots, a_i - a_i, \ldots, a_{|\mathcal{R}|}), & \text{if} & \mathsf{ce}(q) \in A_{=R_i} \, \wedge \\
\qquad (a'_1, \ldots, a'_j - a'_j, \ldots, a'_{|\mathcal{R}|}) & & i < k \, \wedge \\
& & a_i + w_1(\mathsf{ce}(q)) > C_A \, \wedge \\
& & j > i \wedge a'_j < C_B \\[4pt]
(v, k, \; (a_1, \ldots, a_i - a_i, \ldots, a_{|\mathcal{R}|}), & \text{if} & \mathsf{ce}(q) \in B_{=R_j} \, \wedge \\
\qquad (a'_1, \ldots, a'_j - a'_j, \ldots, a'_{|\mathcal{R}|}) & & j > k \, \wedge \\
& & a'_j + w_1(\mathsf{ce}(q)) < C_B \, \wedge \\
& & i < j \wedge a_i > C_A \\[4pt]
(\mathsf{last}(q), i, \; (a_1, \ldots, a_i + w_1(\mathsf{ce}(q)), \ldots, a_{|\mathcal{R}|}), & \text{if} & \mathsf{ce}(q) \in A_{=R_i} \, \wedge \\
\qquad (a'_1, \ldots, a'_{|\mathcal{R}|})) & & i < k \, \wedge \\
& & a_i + w_1(\mathsf{ce}(q)) > C_A \, \wedge \\
& & (\nexists j > i)(a'_j < C_B) \\[4pt]
(\mathsf{last}(q), j, \; (a_1, \ldots, a_{|\mathcal{R}|}), & \text{if} & \mathsf{ce}(q) \in B_{=R_j} \, \wedge \\
\qquad (a_1, \ldots, a'_j + w_1(\mathsf{ce}(q)), \ldots, a'_{|\mathcal{R}|})) & & j > k \, \wedge \\
& & a'_j + w_1(\mathsf{ce}(q)) < C_B \, \wedge \\
& & (\nexists i < j)(a_i > C_A)
\end{array} \tag{12}
$$

We note that if a leaf q is reached, then there are two possibilities as to which node the play continues at. The first case is when σ does not change the sub-strategy σ_k^v (first 5 items in (12)). In this case the play continues at node $\mathsf{ph}(q)$. The second case is when σ does change the sub-strategy σ_k^v (last 2 items in (12)). In this case the play continues at the root ($\mathsf{last}(q)$) of the new tree $T^{\mathsf{last}(q)}$.

Before getting to formal proofs we will describe how the definition of the strategy σ corresponds to what was said in Section 3.1.

While using the sub-strategy σ_k^v, only cycles from $P \cup A_{\leq R_k} \cup B_{\geq R_k}$ are traversed. Moreover, by Lemma 3.5, the effects of the cycles from $A_{=R_k}$ and $B_{=R_k}$ are balanced. The additional memory of the global strategy σ is used to detect an imbalance between the cycles from $A_{<R_k}$ and $B_{>R_k}$. An imbalance is suspected when some a_i such that $i < k$ goes above $C_A = 4 \cdot |V|^4 + 2 \cdot |V|$, or some a_j' such that $j > k$ goes below $C_B = -4 \cdot |V|^4$. However, this does not necessarily imply an imbalance. We will look only at the first case, the other one is symmetric. If some a_i such that $i < k$ goes above C_A, and there is also some $j > i$ such that a_j' is below C_B, then there is no imbalance. The effects of the corresponding cycles from $A_{=R_i}$ and $B_{=R_j}$ balance each other. The bounds were selected so that the sum of the weights of these cycles is greater or equal to $(|V|, |V|)$, which justifies the zeroing of the appropriate elements of the memory (4th item in (12)) and also compensates for the possibly negative simple paths that are "lost" when switching a sub-strategy.

A sub-strategy is changed when there is no a_j' that would compensate for a_i, and so an imbalance occurs. The sub-strategy is changed to σ_i^u where u is the current vertex when the imbalance occurred (6th item in (12)). It holds that $u = \mathsf{last}(q)$ where q is the appropriate leaf in the tree T^v, the visit of which caused the imbalance. The sub-strategy is changed to ensure that a_i is not further increased. The sub-strategy σ_i^u works with the tree T^u, and so the path $\mathsf{ph}(q)$ from v to u is lost in the sense that it is reflected neither in the local nor in the global memory. However, as mentioned above this lost paths are compensated for, and so the global memory together with the local memories gives a lower bound on the first counter, and indirectly also on the second counter. Since all the components of the memories are of polynomial size, so are the lower bounds.

The following lemmas and theorem make the above arguments precise.

Lemma 3.6. Let $a, b, a', b' \in \mathbb{Z}$ be such that $a, b' > 0$, $b, a' < 0$, $\frac{a}{b}, \frac{a'}{b'} \in \mathcal{R} = \{\frac{a}{b} \mid a \in \{-|V|, \ldots, -1\} \wedge b \in \{1, \ldots, |V|\}\}$, and $\frac{a}{b} < \frac{a'}{b'}$. Let further $4 \cdot |V|^4 + 2 \cdot |V| < a \leq 4 \cdot |V|^4 + 3 \cdot |V|$ and $-4 \cdot |V|^4 - |V| \leq a' < -4 \cdot |V|^4$. Then $a + a' \geq |V|$, and $b + b' \geq |V|$.

Proof: Proving $a + a' \geq |V|$ is trivial, let's prove that $b + b' \geq |V|$.

The fact that $\frac{a}{b}, \frac{a'}{b'} \in \mathcal{R}$ implies that also $\frac{b}{a}, \frac{b'}{a'} \in \mathcal{R}$, and the fact that $\frac{a}{b} < \frac{a'}{b'}$ implies that $\frac{b}{a} > \frac{b'}{a'}$, and since $\frac{b}{a}, \frac{b'}{a'} \in \mathcal{R}$, it holds that that $\frac{b}{a} > \frac{b'}{a'} + \frac{1}{|V|^2}$, which can be developed into $a'b < ab' + \frac{1}{|V|^2}aa'$. From the assumptions of the lemma it also follows that $a + a' \leq 3|V|$, which can be developed into $ab + a'b \geq 3|V|b$, and so $ab + ab' + \frac{1}{|V|^2}aa' \geq 3|V|b$. The last inequality can be developed into $a(b + b') \geq 3|V|b - \frac{1}{|V|^2}aa'$, and further into $b + b' \geq 3|V|\frac{b}{a} - \frac{1}{|V|^2}a'$. Since $\frac{b}{a} \in \mathcal{R}$, it holds that $\frac{b}{a} \geq -|V|$. Together with the fact that $a' < -4|V|^4$, it follows that $3|V|\frac{b}{a} - \frac{1}{|V|^2}a' \geq -3|V|^2 + \frac{1}{|V|^2}4|V|^4 = 4|V|^2 - 3|V|^2 = |V|^2 \geq |V|$. Therefore $b + b' \geq |V|$. $\qquad\square$

Lemma 3.7. Let $\Gamma = (G = (V, E, w), V_\square, V_\Diamond)$ be a 2-dim VASS game. Let further $v \in W_\square$ be the starting vertex, and let $\square$ use the strategy σ as defined in (11). Then, every time the sub-strategy of σ is changed to σ_k^v for some $v \in W_\square$ and $k \in \{1, \ldots, |\mathcal{R}|\}$, i.e., the second element of the memory is changed to k, the following holds. Let $(v, k, (a_1, \ldots, a_{|\mathcal{R}|}), (a_1', \ldots, a_{|\mathcal{R}|}'))$ be the state of the memory right after the change. Then, for each $i \in \{1, \ldots, |\mathcal{R}|\}$ such that $i < k$, it holds

that $0 \leq a_i \leq 4 \cdot |V|^4 + 2 \cdot |V|$, and for each $j \in \{1, \ldots, |\mathcal{R}|\}$ such that $j > k$, it holds that $-4 \cdot |V|^4 \leq a'_j \leq 0$.

Proof: We will prove the lemma by induction on the number of times the sub-strategy was changed. We will denote the number by t.

$t = 0$. Right after the 0-th change of the sub-strategy, i.e., at the very beginning of the play, the state of the memory is $(v, 1, (0, \ldots, 0), (0, \ldots, 0))$. Therefore, the claim of the lemma is satisfied. This finishes the induction base.

$t > 0$. From the induction hypothesis, it follows that right after the $(t - 1)$-th change of the sub-strategy, the strategy σ started to use the sub-strategy σ_k^v such that for the state of the memory $(v, k, (a_1, \ldots, a_{|\mathcal{R}|}), (a'_1, \ldots, a'_{|\mathcal{R}|}))$, the following held. For each $i \in \{1, \ldots, |\mathcal{R}|\}$ such that $i < k$, $0 \leq a_i \leq 4 \cdot |V|^4 + 2 \cdot |V|$, and for each $j \in \{1, \ldots, |\mathcal{R}|\}$ such that $j > k$, $-4 \cdot |V|^4 \leq a'_j \leq 0$.

While the strategy σ_k^v was used, each traversed cycle from A was also from $A_{\leq R_k}$, and each traversed cycle from B was also from $B_{\geq R_k}$. The traversed cycles from $A_{=R_k} \cup B_{=R_k}$ did not affect the memory, and so the only parts of the memory the absolute values of which could have been increased while the strategy σ_k^v was used were: a_i for $i < k$ and a'_j for $j > k$. Therefore, if some element exceeded its soft bound, and it is was not the case when the element was zeroed together with its "complementary" element (cf. (12), items 4–5), and so the sub-strategy σ_k^v was changed to some other sub-strategy $\sigma_{k'}^{v'}$ (this is the t-th change of the sub-strategy), then the following held. If $k' > k$, then the element $a'_{k'}$ exceeded its soft bound, i.e., $-4 \cdot |V|^4 - |V| \leq a'_{k'} < -4 \cdot |V|^4$. If $k' < k$, then the element $a_{k'}$ exceeded its soft bound, i.e., $4 \cdot |V|^4 + 2 \cdot |V| < a_{k'} \leq 4 \cdot |V|^4 + 3 \cdot |V|$. Without loss of generality, let $k' > k$. Let's consider the moment right after the t-th change of the sub-strategy and let's prove the claim of the lemma.

For $j > k'$, it holds that $-4 \cdot |V|^4 \leq a'_j \leq 0$, because $k' > k$, and so while the previous strategy σ_k^v was used, the elements a'_j with $j > k'$ never exceeded their soft bounds without being zeroed immediately. Otherwise, the sub-strategy would have been changed earlier.

For $i < k'$, it holds that $0 \leq a_i \leq 4 \cdot |V|^4 + 2 \cdot |V|$, because if for some $i < k'$, it held that $a_i > 4 \cdot |V|^4 + 2 \cdot |V|$, then the sub-strategy would have not been changed to $\sigma_{k'}^{v'}$ and the elements a_i and $a'_{k'}$ would have been zeroed instead, according to (12), item 5. This finishes the induction step, and the lemma is proved. $\square$

Corollary 3.8. While the strategy σ is used, the memory $(v, k, (a_1, \ldots, a_{|\mathcal{R}|}), (a'_1, \ldots, a'_{|\mathcal{R}|}))$ satisfies that for each $i \in \{1, \ldots, |\mathcal{R}|\}$, it holds:

$$
\begin{aligned}
0 \leq \quad a_i \quad &\leq 4 \cdot |V|^4 + 3 \cdot |V| \\
-4 \cdot |V|^4 - |V| \leq \quad a'_i \quad &\leq 0
\end{aligned}
$$

Proof: By Lemma 3.7, only elements a_i such that $0 \leq a_i \leq 4 \cdot |V|^4 + 2 \cdot |V|$ are increased, and only elements a'_j such that $-4 \cdot |V|^4 \leq a'_j \leq 0$ are decreased. $\square$

Theorem 3.9. Let $\Gamma = (G = (V, E, w), V_\square, V_\Diamond)$ be a 2-dim VASS game. Let further $v \in W_\square$ be the starting vertex, and let $\square$ use the strategy σ as defined in (11). Let $\Diamond$ use an arbitrary strategy π, and let $\mathsf{outcome}^\Gamma(v, \sigma, \pi) = (v = v_0, v_1, v_2, \ldots)$ be the resulting play. Let k be the state of the play after k steps, i.e., we are at the vertex v_k. Let $(v', l, (a_1, \ldots, a_{|\mathcal{R}|}), (a'_1, \ldots, a'_{|\mathcal{R}|}))$ be the state of the global memory, and let $(x_i, y_i, z_i)_{i \in \{1, \ldots, |\mathcal{R}|\}}$ be the state of the local memories of the sub-strategies. Then

the following holds:

$$\textstyle\sum_{i=0}^{k-1} w_1(v_i, v_{i+1}) \geq \ \sum_{i\in\{1,...,|\mathcal{R}|\}}(a_i + a'_i + x_i) - |V|^3 - 2 \cdot |V|$$

$$\textstyle\sum_{i=0}^{k-1} w_2(v_i, v_{i+1}) \geq \ \sum_{i\in\{1,...,|\mathcal{R}|\}}(-|V|a_i - \tfrac{1}{|V|}a'_i + y_i) - |V|^3 - 2 \cdot |V|$$

Proof: Consider a continuous sub-path sp of the infinite play corresponding to the use of some sub-strategy σ_i^u. That is, the sub-path sp starts at the point where the sub-strategy of σ was changed to σ_i^u, and ends at the point where the sub-strategy was changed to some other strategy. The sub-path sp consists of cycles from $A_{\leq R_i} \cup B_{\geq R_i} \cup P$ and some remaining "tail" tsp, which is a path in G with no repeated vertex. Since tsp can contain at most $|V|$ vertices, it holds that $w_1(tsp) \geq -|V|$ and $w_2(tsp) \geq -|V|$. When the sub-strategy is changed, the tail is lost in the sense that it is not reflected in the memories. However, by the definition of σ and Lemma 3.5 and Corollary 3.8, these tails and also the cycles from P are the *only* parts of the infinite play that are reflected neither in the global memory nor in the local memories. The cycles from P are not a problem, because they have both weights non-negative. Therefore, we have to prove that the tails are somehow compensated. We will use Lemma 3.6 for this purpose.

By Lemma 3.6, when the elements of the memory a_i and a'_j such that $i < j$ are zeroed, then the sum of the first weights of the corresponding cycles is greater or equal to $|V|$ and the sum of the second weights of the corresponding cycles is also greater or equal to $|V|$. This justifies the zeroing of these elements, and also compensates for at least one lost tail. So it remains to prove that the tails do not pile up faster than they are compensated.

A tail is lost only when the sub-strategy of σ is changed. The change of the sub-strategy indicates that some element a_i or some element a'_j exceeded its soft bound, and there is no "complementary" element. There is no other way for an element a_i to be decreased than the zeroing. Similarly, there is no other way for an element a'_j to be increased than the zeroing. Therefore, the number of not yet compensated tails is equal to the number of elements of the memory that exceeded their soft bounds and have not been zeroed yet. Since $|\mathcal{R}| \leq |V|^2$, Lemma 3.7 implies, that there can be at most $|V|^2 + 1$ not yet compensated tails at each moment of the play. We also have to take into account the path corresponding to the current node p in the current tree T^v the strategy σ is using. This path may also have negative weight, but it is, again, bounded: $w_1(p) \geq -|V| \wedge w_2(p) \geq -|V|$. All in all, the total weight that is not reflected in the memories is, at each moment, greater or equal to $-(|V|^2 + 1) \cdot |V| - |V| = -|V|^3 - 2 \cdot |V|$, in both components of the weight. The first part of the claim of the theorem:

$$\sum_{i=0}^{k-1} w_1(v_i, v_{i+1}) \geq \sum_{i\in\{1,...,|\mathcal{R}|\}} (a_i + a'_i + x_i) - |V|^3 - 2 \cdot |V|$$

follows immediately. The second part of the claim also follows easily. For a cycle $c \in A$ is holds that $w_2(c) \geq -|V| \cdot w_1(c)$, and for a cycle $c \in B$, it holds that $w_2(c) \geq -\frac{1}{|V|}w_1(c)$. Therefore:

$$\sum_{i=0}^{k-1} w_2(v_i, v_{i+1}) \geq \sum_{i\in\{1,...,|\mathcal{R}|\}} (-|V|a_i - \frac{1}{|V|}a'_i + y_i) - |V|^3 - 2 \cdot |V|$$

$\hfill\square$

Corollary 3.10. Let $\Gamma = (G = (V, E, w), V_\square, V_\lozenge)$ be a 2-dim VASS game. Let further $v \in W_\square$ be the starting vertex, and let $\square$ use the strategy σ as defined in (11). Let $\lozenge$ use an arbitrary strategy π,

and let $\mathsf{outcome}^\Gamma(v, \sigma, \pi) = (v = v_0, v_1, v_2, \dots)$ be the resulting play. Let k be the state of the play after k steps, i.e., we are at the vertex v_k. Then the following holds:

$$\textstyle\sum_{i=0}^{k-1} w_1(v_i, v_{i+1}) \geq \quad -4 \cdot |V|^6 - 2 \cdot |V|^4 - 2 \cdot |V|^3 - 2 \cdot |V|$$

$$\textstyle\sum_{i=0}^{k-1} w_2(v_i, v_{i+1}) \geq \quad -4 \cdot |V|^7 - 5 \cdot |V|^4 - |V|^3 - 2 \cdot |V|$$

Proof: The corollary follows from Theorem 3.9 and the following facts. For each i, $0 \leq a_i \leq 4 \cdot |V|^4 + 3 \cdot |V|$, and $-4 \cdot |V|^4 - |V| \leq a_i' \leq 0$, by Corollary 3.8, and $-2 \cdot |V|^2 \leq x_i, y_i \leq 2 \cdot |V|^2$, by Lemma 3.5. $\qquad\square$

We have proved that for $K = 4 \cdot |V|^7 + 5 \cdot |V|^4 + |V|^3 + 2 \cdot |V|$, each play $(v_0, v_1, v_2, \dots)$ with $v_0 \in W_\square$, agreeing with the strategy σ, satisfies $(\forall k \in \mathbb{N}_0)(\sum_{i=0}^{k-1} w(v_i, v_{i+1}) \geq (-K, -K))$. In the following section we will show how this fact can be used to design a polynomial algorithm for solving 2-dim VASS games.

4. Reduction of a 2-dim VASS Game to a Reachability Game

Let $\Gamma = (G = (V, E, w), V_\square, V_\lozenge)$ be a 2-dim VASS game. The main part of this paper is aimed at proving that there is a constant $K \in \mathbb{N}_0$ of polynomial size with respect to $|V|$ such that $\square$ can win from each $v \in W_\square$ with initial counter values (K, K). In this section, we will show that *all minimal* sufficient initial counter values for all starting vertices $v \in W_\square$ have both counter values of polynomial size with respect to $|V|$.

Let $v \in W_\square$, the configuration $(v, (K, K))$ is a winning starting configuration of $\square$, and $K \in \mathbb{N}_0$ is of polynomial size with respect to $|V|$. Let $(v, (a, b))$ be a winning starting configuration such that $a < K$. We will show that $(v, (a, (|V|+1) \cdot K))$ is also a winning starting configuration. By symmetry, this implies that if $b < K$, then $(v, ((|V| + 1) \cdot K, b))$ is a winning starting configuration. Together, we will have that all minimal winning starting configurations have counter values of polynomial size with respect to $|V|$. So, let's show that $(v, (a, (|V| + 1) \cdot K))$ is a winning starting configuration. To this end we will propose a different valuation for the tree T^v than in the Section 3.2.

Let $q = (v = v_0, \dots, v_k) \in T_V^v$ be a leaf of the tree T^v, then

$$\mathsf{value2}(q) = \begin{cases} \mathbf{0} & \text{if} \quad v_k \in W_\lozenge \\ \mathbf{0} & \text{if} \quad v_k \in W_\square \wedge \mathsf{ce}(q) \in N \cup B \\ \mathbf{0} & \text{if} \quad v_k \in W_\square \wedge \mathsf{ce}(q) \in A \cup P \wedge \min_{i \in \{0, \dots, k\}} w_1(v_0, \dots, v_i) + a < 0 \\ \mathbf{1} & \text{if} \quad v_k \in W_\square \wedge \mathsf{ce}(q) \in A \cup P \wedge \min_{i \in \{0, \dots, k\}} w_1(v_0, \dots, v_i) + a \geq 0 \end{cases}$$

The value of an inner node $p \in T_V^v$ is defined in the following way.

$$\mathsf{value2}(p) = \begin{cases} \mathbf{0} & \text{if} \quad \mathsf{last}(p) \in V_\square \wedge \\ & \qquad (\forall (p, q) \in T_E^v)(\mathsf{value2}(q) = \mathbf{0}) \\ \mathbf{0} & \text{if} \quad \mathsf{last}(p) \in V_\lozenge \wedge \\ & \qquad (\exists (p, q) \in T_E^v)(\mathsf{value2}(q) = \mathbf{0}) \\ \mathbf{1} & \text{if} \quad \mathsf{last}(p) \in V_\square \wedge \\ & \qquad (\exists (p, q) \in T_E^v)(\mathsf{value2}(q) = \mathbf{1}) \\ \mathbf{1} & \text{if} \quad \mathsf{last}(p) \in V_\lozenge \wedge \\ & \qquad (\forall (p, q) \in T_E^v)(\mathsf{value2}(q) = \mathbf{1}) \end{cases}$$

It must be the case that the value of the root (v) is $\mathsf{value2}((v)) = \mathbf{1}$, because if $\mathsf{value2}((v)) = \mathbf{0}$, then the following holds.

The player $\Diamond$ can ensure that each reached leaf q has $\mathsf{last}(q) \in W_\Diamond$, or it corresponds to a cycle from $N \cup B$, or a cycle from $A \cup P$ such that the first weight of some prefix of q is smaller than $-a$. This is in contradiction with the fact that $(v, (a, b))$ is a winning starting configuration, because $\Diamond$ can ensure that the first counter is decreased by more than a, or, in case cycles c from N such that $w_1(c) = 0 \wedge w_2(c) < 0$ are traversed, $\Diamond$ can ensure that the second counter is decreased by more than b. Therefore, it must be the case that $\mathsf{value2}((v)) = \mathbf{1}$.

The fact that the root has the value $\mathbf{1}$ implies that $\Box$ can win either by traversing only cycles from P, or he can "pump" the content of the second counter to the first counter by traversing cycles from A. Each cycle $c \in A$ has $w_1(c) \geq 1$ and $w_2(c) \geq -|V|$. Therefore, if we start with counter values $(a, (|V| + 1) \cdot K)$, we can reach a configuration $(v', (a', b'))$ such that $v' \in W_\Box$ and $a', b' \geq K$. By properties of K, this is a winning configuration, and so $(v, (a, (|V| + 1) \cdot K))$ is also a winning configuration. Together, we have that all minimal winning configurations for $\Box$ have counter values of polynomial size with respect to $|V|$. More specifically, the counter values of all minimal winning configurations are less or equal to $((|V| + 1) \cdot K, (|V| + 1) \cdot K)$, i.e., for $v \in W_\Box$, for each pair of minimal sufficient initial counter values, (a, b), it holds that $(a, b) \leq ((|V| + 1) \cdot K, (|V| + 1) \cdot K)$. This can be used to prove that there is a polynomial time algorithm for solving 2-dim VASS games. Γ corresponds to an infinite reachability game defined as follows.

$$\mathcal{M} = (V \times \mathbb{N}_0^2, \rightarrow, V_\Box \times \mathbb{N}_o^2, V_\Diamond \times \mathbb{N}_0^2)$$

where the components are: the set of configurations, transition relation, configurations belonging to $\Box$, and configurations belonging to $\Diamond$, respectively. The transition relation is defined as follows: $(v, (a, b)) \rightarrow (v', (a', b'))$ if and only if

$$(v, v') \in E \wedge$$
$$(a, b), (a', b') \geq (0, 0) \wedge$$
$$(a', b') = (a + w_1(v, v'), b + w_2(v, v'))$$

$\Box$ wins in $\mathcal{M}$ if and only if he is able to avoid the configurations from the set $\mathsf{Z} = \{(v, (a, b)) \mid a = 0 \vee b = 0\}$. We can define the following restriction of $\mathcal{M}$:

$$\mathcal{M}' = (V \times F^2, \rightarrow', V_\Box \times F^2, V_\Diamond \times F^2)$$

where $F = \{0, \ldots, (|V| + 1) \cdot K\}$ and the components are: the set of configurations, transition relation, configurations belonging to $\Box$, and configurations belonging to $\Diamond$, respectively. The transition relation is defined as follows: $(v, (a, b)) \rightarrow' (v', (a', b'))$ if and only if

$$(v, v') \in E \wedge$$
$$(0, 0) \leq (a, b), (a', b') \leq ((|V| + 1) \cdot K, (|V| + 1) \cdot K) \wedge$$
$$(a', b') = (\min(a + w_1(v, v'), (|V| + 1) \cdot K), \min(b + w_2(v, v'), (|V| + 1) \cdot K))$$

In particular, each increase of either counter above $(|V| + 1) \cdot K$ is truncated to $(|V| + 1) \cdot K$.

Since the counter values of all minimal winning configurations are less or equal to $((|V| + 1) \cdot K), (|V| + 1) \cdot K)$, $\mathcal{M}'$ contains all the minimal winning configurations of the whole reachability game $\mathcal{M}$, and so the solution of $\mathcal{M}'$ directly gives the solution of the original game $\mathcal{M}$ (Recall that the game is upward-closed) and thus it also gives the solution of Γ. Since a reachability game can

be solved in polynomial time with respect to the number of its configurations, the polynomial size of K implies a polynomial time algorithm for the solution of $\mathcal{M}$. As shown in Section 3.5, K can be taken so that $K \in O(|V|^7)$, and so the reduction-to-reachability-game method presented in this section gives us an $O(|V|^{17})$ algorithm for solving 2-dim VASS games. The reachability game has $O(|V|^{16})$ configurations and $O(|V|^{17})$ transitions, and since a reachability game can be solved in time linear with respect to the number of its transitions, we get the complexity $O(|V|^{17})$.

Before we conclude the paper, we briefly discuss how our results can be extended to 2-dim VASS games with symbolic components in edge-weights.

5. 2-dim VASS Games with Symbolic Edge-Weights

Let $\Gamma = (G = (V, E, w), V_\square, V_\diamond)$ be a 2-dim VASS game. In addition to the original definition, we now allow symbolic components, denoted by ω, in edge-weights. So, the weight function is $w : E \to \{-1, 0, 1, \omega\}^2$. The intuitive meaning of ω is "add an arbitrarily large non-negative integer to the appropriate counter". For example, let's suppose there is an edge (v, u) with $w(v, u) = (1, \omega)$, then from each configuration $(v, (a, b))$, there is an infinite number of successors $\{(v, (a + 1, b + x)) \mid x \in \mathbb{N}_0\}$. In the following, we describe how to extend our proofs to 2-dim VASS games with symbolic components.

Central to our proofs is the division of the simple cycles of G into the sets N, P, A, and B, and further division of the cycles from the sets A and B. In this section, we will describe how to incorporate the cycles with symbolic edge-weights into the division.

Let $a_1, \ldots, a_k \in \{-1, 0, 1, \omega\}$. For simplicity, we will define $\sum_{i=1}^{k} a_i = \omega$ if some $a_i = \omega$. Now let c be a simple cycle in G. If $w_1(c) \neq \omega \wedge w_2(c) \neq \omega$, then c is classified as usual. If $w_1(c) = \omega \wedge w_2(c) \neq \omega \wedge w_2(c) \geq 0$ or $w_1(c) \neq \omega \wedge w_1(c) \geq 0 \wedge w_2(c) = \omega$ or $w_1(c) = \omega \wedge w_2(c) = \omega$, then c is classified as a cycle from P. It remains to consider the cycles with one component negative and the other one equal to ω. We will first consider the case where $w_1(c) = \omega \wedge w_2(c) < 0$.

The cycle c with $w_1(c) = \omega \wedge w_2(c) < 0$ is classified as a cycle from A. An important property of the cycles from A is the ratio of $w_1(c)$ and $w_2(c)$. The smaller the ratio, the better it is for player $\square$. It is obvious that the cycle c is better than all the cycles from A without symbolic edge-weights. Therefore, we introduce a new ratio $R_0 = -|V| - 1$. Please note that $-|V|$ is the best possible ratio of A cycles without symbolic edge-weights. Let's now consider the case where $w_1(c) < 0 \wedge w_2(c) = \omega$.

The cycle c with $w_1(c) < 0 \wedge w_2(c) = \omega$ is classified as a cycle from B. Important property of the cycles from B is the ratio of $w_1(c)$ and $w_2(c)$. The bigger the ratio, the better it is for player $\square$. It is obvious that the cycle c is better than all the cycles from B without symbolic edge-weights. Therefore, we introduce a new ratio $R_{|\mathcal{R}|+1} = -\frac{1}{|V|+1}$. Please note that $-\frac{1}{|V|}$ is the best possible ratio of B cycles without symbolic edge-weights.

Now that the cycles with ω weights have been classified, the proofs work just as well as for the case where $w : E \to \{-1, 0, 1\}^2$ (Only some bounds have to be adjusted, but they still remain polynomial). From the above, it also follows that if we replace each occurrence of ω with $|V| \cdot (|V| + 1)$, the sets $W_\square$ and $W_\diamond$ remain the same. To keep the edge-weights in $\{-1, 0, 1\}^2$, we can replace the edges with some component equal to ω by an appropriate number (polynomial with respect to $|V|$) of new edges and vertices such that the weight of each new edge is in $\{-1, 0, 1\}^2$.

6.　Conclusion

We have proved that games on 2-dimensional vector addition systems with states (2-dim VASS games) can be solved in polynomial time. In the proof, we first showed that if □ is able to win from some vertex, then he is able to win from that vertex with initial counter values (a, b) such that a and b are bounded by a fixed polynomial in $|V|$. This allowed us to reduce the Z-reachability problem for 2-dim VASS games to a reachability game problem. The resulting reachability game has an arena of polynomial size with respect to the number of vertices of the input 2-dim VASS game, and since reachability games can be solved in polynomial time, we got the desired result.

　　An interesting open question is whether the techniques presented in this paper can be extended to three- (or even more-) dimensional VASS games. Since the presented results about 2-dimensional VASS are relatively complicated, we suspect this problem as difficult.
